All thyroid diseases are encountered in the elderly; however, their prevalence and clinical expression differ from those observed in younger patients. Symptoms of aging can be confused easily with hypothyroidism. The clinical manifestations of thyroid dysfunction can be more vague, subtle, and hidden by a background of coexistent disease. Interpretation of thyroid function studies can be problematic in elderly patients, owing to difficulty in differentiating physiologic age-associated changes from alterations secondary to acute or chronic nonthyroidal illnesses [5]. And finally, the medical and surgical treatment of thyroid disease in the elderly is associated with an increased risk of complications attributed to the treatment itself [6].

Thyroid Function

The thyroid gland synthesizes the hormones thyroxine (T_4) and triiodothyronine (T_3), iodine-containing amino acids that regulate the body's metabolic rate. Adequate levels of thyroid hormone are necessary in infants for normal development of the central nervous system, in children for normal skeletal growth and maturation, and in adults for normal function of multiple organ systems [7]. Thyroid dysfunction is one of the most common endocrine disorders encountered in clinical practice. While abnormally high or low levels of thyroid hormones can be tolerated for long periods of time, usually there are symptoms and signs of thyroid dysfunction.

The effects of thyroid hormones are diffuse and important (Table 34.1). Thyroid hormones increase the activity of membrane-bound Na^+K^+ adenosine triphosphate (ATP)-ase, increase heat production, and stimulate oxygen consumption (“calorigenesis”). Thyroid hormones also affect tissue growth

and maturation, help regulate lipid metabolism, increase cardiac contractility by stimulating the expression of myosin protein, and increase intestinal absorption of carbohydrates (Fig. 34.1) [8].

The usual biochemical measures of thyroid function, such as T_3 , T_4 , and thyroid-binding protein levels, change little with advancing age in the absence of systemic illness. Similarly, thyrotropin (TSH) levels and the production of

TABLE 34.1 Physiologic effects of thyroid hormones

Target tissue	Effect	Mechanism
Heart	Chronotropic	Increase number and affinity of beta-adrenergic receptors
	Inotropic	Enhance responses to circulating catecholamines
		Increase proportion of alpha myosin heavy chain (with higher ATPase activity)
Adipose tissue	Catabolic	Stimulate lipolysis
Muscle	Catabolic	Increase protein breakdown
Bone	Developmental and metabolic	Promote normal growth and skeletal development; accelerate bone turnover
Nervous system	Developmental	Promote normal brain development
Gut	Metabolic	Increase rate of carbohydrate absorption
Lipoprotein	Metabolic	Stimulate formation of LDL receptors
Other	Calorigenic	Stimulate oxygen consumption by metabolically active tissues (exceptions: adult brain, testes, uterus, lymph nodes, spleen, anterior pituitary)
		Increase metabolic rate

ATP adenosine triphosphate; LDL low-density lipoprotein

TSH in response to thyrotropin-releasing hormone (TRH) administration are relatively constant with increasing age [9]. In the past, hypothyroidism was considered an integral part of aging; however, more recent studies suggest that physiologic aging is associated with normal thyroid function [10]. The half-life of T_4 increases from 6.7 days in young adults to 9.3 days in those aged 80–90 years due to decreases in both fractional turnover rate and the distribution space of T_4 . Peripheral conversion of T_4 – T_3 is decreased, but the intrathyroidal conversion is increased, resulting in relatively stable T_3 levels in the elderly [11].

The Wickham survey documented the prevalence of thyroid disorders in a sample of 2,779 British adults, and the 20-year follow-up study was published in 1995 [12, 13]. The annual incidence of hypothyroidism was found to increase with age and correlate with the presence of thyroid autoantibodies or elevated TSH levels. Aging often is associated with an increased prevalence of antithyroid antibodies, but this age-dependent increase is observed commonly in unselected elderly subjects and not in healthy elderly populations selected for the absence of clinical or subclinical illnesses [14]. This suggests that thyroid autoimmune phenomena may not be the consequence of the aging process itself but, rather, an expression of age-associated disease.

Thyroid Dysfunction

Thyroid function can be evaluated by several biochemical measures, including total or free T_3 and T_4 , and TSH [15]. The high incidence of comorbid illness in elderly people can confound assessment of thyroid function. Malnutrition, infection, sepsis, major surgery, poorly controlled diabetes mellitus, hepatic disease, renal failure, cerebrovascular disease, heart failure, malignancy, trauma, burns, and coma are all associated with alterations in thyroid function tests [16]. Depending on severity, stage, and drug effects, these nonthyroidal illnesses are associated with changes in the parameters of thyroid function that include low serum T_3 , normal to low T_4 , and normal to low or elevated TSH – the “euthyroid sick syndrome.” Among acutely ill patients, 70% show a low T_3 state, and 30–50% of patients in intensive care units have low serum T_4 levels [17].

Findings in patients’ personal and family histories indicate increased risk of developing thyroid dysfunction. Risk factors in personal history include goiter, surgery or radiotherapy affecting the thyroid gland, previous thyroid dysfunction, vitiligo, diabetes mellitus, pernicious anemia, leukotrichia, and medications, such as lithium carbonate and amiodarone, and iodine-containing compounds. Pertinent factors in family history are thyroid disease, pernicious anemia, diabetes mellitus, and primary adrenal insufficiency [18].

Measurement of serum TSH, a sensitive indicator of free thyroid hormone concentration in the presence of normal pituitary function, is often all that is required as a screening test for thyroid function. A decision analysis by Danese et al. reported that screening for thyroid disease by TSH measurement was particularly cost-effective in elderly female patients, as the clinical symptoms of thyroid dysfunction may be atypical in this age group [19]. Analyses of free hormone levels determine what is available for cellular metabolic regulation. In addition to thyroid function tests, diagnostic determination of thyroid autoantibodies can be useful. Antibodies to the TSH receptor are present in Graves’ disease and also can be seen with other forms of autoimmune thyroid disease, such as Hashimoto’s thyroiditis. Antithyroid peroxidase antibodies and antithyroglobulin antibodies are seen with all forms of autoimmune thyroid disease and may be present in patients with multinodular goiter. Assessment of the thyroid also should include imaging studies, such as ultrasound, nuclear medicine uptake scans, computed tomography (CT) scans, and magnetic resonance imaging (MRI).

Hypothyroidism

Epidemiology

The balance between central production and peripheral action of T_3 and T_4 is required for a euthyroid state. Clinical hypothyroidism usually is associated with decreased hormone production in the thyroid gland, although states of limited thyroid hormone activity in the periphery also can occur. In many underdeveloped countries or iodine-poor regions, lack of sufficient iodine intake explains a large percentage of hypothyroid conditions [20, 21]. In more developed countries, most cases of adult primary hypothyroidism (due to direct thyroid failure) are secondary to chronic autoimmune (Hashimoto’s) thyroiditis, radioactive iodine (RAI) therapy, or surgery. Disorders of the pituitary or hypothalamus can cause diminished TSH secretion, producing hypothyroidism as a secondary or tertiary result. Finally, a host of medications, including the thioamide antithyroid drugs propylthiouracil (PTU) and methimazole (MMI), can produce hypothyroidism (Table 34.2).

There are two types of primary hypothyroidism. Clinical or overt primary hypothyroidism is characterized by elevated serum TSH and decreased serum T_3 and T_4 levels. Patients with subclinical primary hypothyroidism show mildly elevated serum TSH concentrations and normal serum thyroid hormone levels. Subclinical hypothyroidism is the most common thyroid dysfunction nationwide, with a markedly increased prevalence in the elderly, ranging from 4 to 15%

TABLE 34.2 Causes and pathogenetic mechanisms of hypothyroidism

Etiologic classification	Pathogenetic mechanism
Congenital	
	Aplasia or hypoplasia of thyroid gland
	Defects in hormone biosynthesis or action
Acquired	
Hashimoto's thyroiditis	Autoimmune destruction
Severe iodine deficiency	Diminished hormone synthesis, release
Thyroid ablation	Diminished hormone synthesis, release
Thyroid surgery	
¹³¹ I radiation treatment of hyperthyroidism	
External beam radiation therapy for head and neck cancer	Diminished hormone synthesis, release

for subclinical hypothyroidism and from 0.5 to 6% for overt hypothyroidism [22]. In the Whickham study, the risk of developing hypothyroidism was significantly increased in women between 75 and 80 years [12, 13].

Clinical and Diagnostic Evaluation

A comprehensive medical history should uncover symptoms that help establish the diagnosis, such as cold intolerance, weight gain, diminished appetite, constipation, and lethargy. On physical examination, a patient may exhibit hoarseness, bradycardia, periorbital or ankle edema, generalized muscle weakness, or delayed relaxation of deep tendon reflexes. The suspicion of hypothyroidism is raised by unexplained increases in serum cholesterol and creatine phosphokinase levels, severe constipation, congestive heart failure with restrictive cardiomyopathy, or macrocytic anemia [9].

Hypothyroidism is characterized by abnormally low serum T_4 and T_3 levels. Free thyroxine levels also are depressed. The serum TSH level is elevated in hypothyroidism, except in cases of pituitary or hypothalamic disease. TSH is the most sensitive test for early hypothyroidism, and

TABLE 34.3 Clinical findings in adult hypothyroidism

Symptoms
Slow thinking
Lethargy, decreased vigor
Dry skin, thickened hair, hair loss, broken nails
Diminished food intake, weight gain
Constipation
Menorrhagia, diminished libido
Cold intolerance
Signs
Round puffy face, slow speech, hoarseness
Hypokinesia, generalized muscle weakness, delayed deep tendon reflexes
Cold, dry, thick, scaling skin; dry, coarse, brittle hair; dry, ridged nails
Periorbital edema, ascites, pericardial effusion, ankle edema
Normal or faint cardiac impulse, indistinct heart sounds, bradycardia
Mental clouding, depression
Laboratory findings
Increased serum TSH
Decreased serum free thyroxine, total T_4 and T_3 , resin T_4 or T_3 uptake, free thyroxine index
Decreased radioiodine uptake by thyroid gland
Diminished basal metabolic rate
Macrocytic anemia
Elevated serum cholesterol, creatine kinase
Decreased circulation time, low-voltage QRS complex on EKG

marked elevations of serum TSH (>20 mU/L) are consistent with frank hypothyroidism. Modest TSH elevations (5–20 mU/L) may be found in euthyroid individuals with normal serum T_3 and T_4 levels and indicate impaired thyroid reserve and incipient hypothyroidism (Table 34.3) [23].

Many features of hypothyroidism are insidious and can be incorrectly attributed to aging. Hypothyroidism in elderly patients can be characterized by a paucity of specific signs and symptoms. Because of the high prevalence of hypothyroidism in women over 60 years, it is recommended that such individuals undergo annual screening with serum TSH measurement [24]. In addition, patients with other autoimmune diseases and those with unexplained depression or cognitive dysfunction should be screened with TSH measurements [25].

Treatment

The goal of therapy is to restore patients to a euthyroid state and normalize serum T_4 and TSH concentrations. Levothyroxine sodium, with its longer half-life and more stable serum concentration, is the treatment of choice for the routine management of hypothyroidism. Adults with hypothyroidism require approximately 1.7 mcg/kg of body weight per day for full replacement. For patients who are older than

50 years, a lower initial dosage is indicated, starting with 0.025–0.05 mg of levothyroxine daily, with clinical and biochemical reevaluations at 6- to 8-week intervals until serum TSH concentration is normalized [16]. In elderly patients with coexistent or suspected cardiac disease, levothyroxine therapy may precipitate angina or myocardial infarction. This is due to sensitivity to the hormone as a result of chronic depletion of catecholamines in the myocardium [10]. Monitoring serum TSH levels to ensure that they remain in the normal range will prevent the potential risk of overtreatment with levothyroxine.

Patients with subclinical hypothyroidism also can benefit from levothyroxine therapy. As many as 15% of elderly patients with subclinical hypothyroidism progress to overt hypothyroidism, particularly if the TSH concentration is greater than 10 mU/mL and thyroid autoantibodies are elevated [26]. Although early treatment prevents progression to frank hypothyroidism, hormone replacement therapy may exacerbate underlying cardiac disease. The decision whether to treat subclinical hypothyroidism should be made on an individual basis.

Hyperthyroidism

Epidemiology

The disease processes associated with increased thyroid secretion result in a hypermetabolic state. Increased thyroid secretion can be caused by primary alterations within the gland, most commonly due to Graves' disease in which TSH receptor autoantibodies stimulate thyroid follicular cells to produce excessive amounts of T_3 and T_4 . Toxic adenoma (TA) and toxic multinodular goiter (TMNG, also known as Plummer's disease) are other common causes of hyperthyroidism, second in prevalence only to Graves' disease. They can appear at any age, although they most frequently occur in patients older than 40 years. Unlike Graves' disease, TA and TMNG are not believed to have an autoimmune etiology, since TSH receptor autoantibodies are absent. Less commonly, patients with multinodular goiter may become thyrotoxic without circulating antibodies if administered inorganic iodine compounds such as potassium iodide, or organic iodine compounds, such as the antiarrhythmic drug amiodarone. Patients from regions where goiter is endemic, so-called goiter belts, can develop thyrotoxicosis when given iodine supplementation (Jod-Basedow phenomenon) [20, 21]. Rarely, TSH-secreting pituitary adenomas (secondary hyperthyroidism) or TRH-secreting hypothalamic disorders (tertiary hyperthyroidism) may occur. Most hyperthyroid states result from thyroid gland dysfunction (Table 34.4). It is important to remember that thyrotoxicosis in the elderly can be caused easily by the administration of exogenous thyroid hormone.

TABLE 34.4 Causes and pathogenetic mechanisms of hyperthyroidism

Etiologic classification	Pathogenetic mechanism
Thyroid hormone overproduction	
Graves' disease	TSH-R-stimulating antibody
Toxic multinodular goiter	Autonomous hyperfunction
Follicular adenoma	Autonomous hyperfunction
Pituitary adenoma	TSH hypersecretion
Pituitary insensitivity	Resistance to thyroid hormone
Hypothalamic disease	Excess TRH production
Germ cell tumors	hCG stimulation
Struma ovarii	Functioning thyroid elements
Metastatic follicular thyroid cancer	Functioning metastases
Thyroid gland destruction	
Granulomatous thyroiditis	Release of stored hormone
Hashimoto's thyroiditis	Transient release of stored hormone
Other	
Thyrotoxicosis medicamentosa, thyrotoxicosis factitia	Ingestion of excessive exogenous thyroid hormone

TSH-R thyroid-stimulating hormone-receptor, *TRH* thyrotropin-releasing hormone, *hCG* human chorionic gonadotropin

There are two types of primary hyperthyroidism based on thyroid function tests. Clinical primary hyperthyroidism is characterized by suppressed serum TSH and elevated serum total T_4 levels. Subclinical primary hyperthyroidism is defined by suppressed TSH and normal T_4 and T_3 levels. The prevalence of hyperthyroidism in the elderly ranges from 0.5 to 2.3% [27]. The Wickham survey demonstrated that hyperthyroidism did not increase in frequency with age or positive autoantibody status [12, 13]. Approximately 5% of elderly patients have subclinical hyperthyroidism [10].

Clinical and Diagnostic Evaluation

A detailed medical history will usually reveal sufficient clues to suggest the diagnosis of hyperthyroidism. Classic symptoms include heat intolerance, weight loss, increased appetite, palpitations, and emotional lability. Physical examination findings may include hyperkinesia, lid lag, periorbital edema, proptosis, proximal muscle weakness, and tachycardia (Table 34.5). Elderly hyperthyroid patients can display few signs and symptoms; this has been referred to as "apathetic hyperthyroidism." Orbital signs are often lacking with the exception of Graves' ophthalmopathy, which, if present, is usually worse than eye disease in the young (Fig. 34.2). Tachycardia in older patients is less common than that in younger patients, although it can be found in up to 50% of older patients. Congestive heart failure and angina are more frequent. Atrial fibrillation in thyrotoxic patients ranges from 9 to 22%, with a higher prevalence in elderly male patients [9]. Several studies also have demonstrated subtle abnormalities

TABLE 34.5 Clinical findings in adult hyperthyroidism

Symptoms
Alertness, emotional lability, nervousness, irritability
Poor concentration
Muscular weakness, fatigability
Palpitations
Voracious appetite, weight loss
Hyperdefecation
Heat intolerance
Signs
Hyperkinesia, rapid speech
Proximal muscle weakness, fine tremor
Fine, moist skin; fine, abundant hair; onycholysis
Lid lag, stare, chemosis, periorbital edema, proptosis
Accentuated first heart sound, tachycardia, atrial fibrillation, dyspnea
Laboratory findings
Suppressed serum TSH
Elevated serum free thyroxine, total T ₄ , resin T ₃ or T ₄ uptake, free thyroxine index
Increased radioiodine uptake by thyroid gland
Increased basal metabolic rate
Decreased serum cholesterol

**FIGURE 34.2** Exophthalmos in Graves' disease.

of cardiac contractility in individuals with subclinical hyperthyroidism, and one prospective study found that patients over age 65 years with TSH <0.1 mU/L had a threefold greater risk of developing atrial fibrillation than those with normal TSH levels [27]. Depression, lethargy, agitation, anxiety, dementia, and confusion have been reported as primary manifestations [26]. Because overt hyperthyroidism results in bone loss – through reduced absorption of dietary calcium, increased calcium excretion, increased bone turnover, and ultimately, decreased bone mineral density – the increased risk of osteoporosis and pathologic fracture is a pertinent feature of thyrotoxicosis in the elderly.

Treatment

Treatment of hyperthyroidism is directed toward lowering serum concentrations of thyroid hormones to reestablish

TABLE 34.6 Adverse effects of major treatment modalities for hyperthyroidism

Treatment	Adverse effects
Antithyroid drugs (methimazole, propylthiouracil)	1–15% rash, arthralgias, fever, urticaria Rare: fulminant hepatitis, acute hepatic necrosis, glomerulonephritis, lupus-like syndrome, cholestatic hepatitis 15–30%: elevated transaminases within first 2 months of therapy 0.2–0.5%: agranulocytosis within first 3 months of therapy
Radioactive iodine	Transient or permanent hypothyroidism Recurrent or persistent hyperthyroidism Radiation thyroiditis Transient worsening of ophthalmopathy Hyperparathyroidism Thyrotoxic crisis Secondary gastrointestinal malignancy Radiation safety precautions
Surgery	Hypothyroidism Hypoparathyroidism Recurrent laryngeal nerve injury Hemorrhage Risk of anesthesia

a euthyroid state. There are three available modalities of treatment: antithyroid medications, radioactive iodine (¹³¹I) therapy, and thyroid surgery. Each modality carries risks and benefits (Table 34.6).

Antithyroid Medication

Antithyroid medications interfere with one or more steps in the biosynthesis and secretion of thyroid hormone and include MMI and PTU. MMI is the preferred drug. Initial doses are MMI 10–40 mg three times daily and PTU 100–300 mg three times daily; these then can be reduced to once-daily dosing after the patient is rendered euthyroid. Rapidity of response is influenced by severity of the underlying disease, size of the gland, and dose and frequency of the agent used. In general, patients become euthyroid within 6–12 weeks of starting treatment [24].

Adverse reactions to both medications occur, including pruritus, arthralgias, and hepatic abnormalities. Hepatic necrosis caused by PTU and cholestatic jaundice associated with MMI are rare but recently have been the focus of attention. Agranulocytosis in response to either drug occurs in approximately 0.3% of patients, supporting routine monitoring of white blood cell counts [24]. In addition, Imseis and colleagues demonstrated that treatment with PTU reduced the efficacy of RAI therapy, an effect that was not found with MMI use [28]. This is of critical importance for patients who do not respond appropriately to antithyroid medications.

Long-term therapy can lead to remission, but as many as 40% of patients fail to remit after 2 years of treatment. The recurrence rate of disease is 60% after 6 months of therapy, with a latent period of 2–6 weeks. Because of this high failure rate, medical therapy with curative intent is primarily indicated in patients with small goiters, mildly elevated thyroid hormone levels, and who exhibit rapid remission with reduction of gland size [29].

In addition to preventing further synthesis of thyroid hormone, blockade of the catecholamine effects of thyroid hormone is especially important in elderly patients with underlying cardiac disease. The most useful adjuncts are beta-adrenergic blockers, which can provide symptomatic relief. Unfortunately, beta-blockers are contraindicated in patients with asthma or chronic obstructive pulmonary disease and those with heart block and congestive heart failure. In these patients, a calcium channel blocker such as diltiazem may be substituted [10, 24].

Radioactive Iodine Therapy

Radioactive iodine therapy (RAI) therapy is the standard treatment for thyrotoxicosis of Graves' disease in the USA. TMNG and toxic adenoma respond to ^{131}I , but surgery is more commonly employed. Advantages of RAI are avoidance of daily medications with the associated risk of noncompliance, symptoms of hyperthyroidism, and the risk of surgery. Thyrotoxic atrial fibrillation is likely to revert to sinus rhythm after a euthyroid state is established [10]. The overall risk of hypothyroidism with RAI necessitating lifelong replacement therapy is approximately 6% at 1 year and 82% at 25 years [30]. The insidious development of hypothyroidism is likely to occur following ^{131}I administration, and most patients eventually will require lifelong thyroid hormone replacement. Euthyroidism can take 4–6 months to achieve, and multiple doses may be required [29]. Because the effects of RAI may not be immediately evident, surgical resection in patients with antithyroid drug allergies, large goiters, more urgent cardiac issues, or coincident thyroid cancer may be more favorable.

In the USA, treatment of Graves' disease with RAI is the preferred therapy for most patients over the age of 21 years. Follow-up studies have not implicated RAI as a risk factor for development of secondary malignancies [31]. The main side effect of RAI is the development of hypothyroidism; most often, this occurs in patients with severe hyperthyroidism or very large goiters. Pretreatment with antithyroid medications before RAI reduces its effectiveness, primarily due to a radioactive-iodine-uptake (RAIU) independent effect [32]. This is particularly a problem with PTU, which can have a radioprotective effect [28]. However, in patients with severe hyperthyroidism, particularly in the presence of cardiac comorbidity, antithyroid medication pretreatment should

be performed for 4–8 weeks before RAI. Pretreatment reduces thyroid hormone secretion rapidly and thereby reduces the risk of thyrotoxic crisis soon after RAI [33].

The effect of RAI for Graves' hyperthyroidism associated with significant ophthalmopathy is controversial. In a prospective randomized study, Bartalena et al. evaluated the effects of RAI versus antithyroid medications and the effects of glucocorticoids in patients with or without Graves' ophthalmopathy. Among those treated with RAI, ophthalmopathy developed or worsened in 15% of patients 2–6 months after therapy. None of the patients with baseline ophthalmopathy in this group had improvement of eye disease. Among patients treated with a combination of RAI and glucocorticoids, 67% of patients with ophthalmopathy had improvement, and no patients had progression of eye disease [34].

RAI also provides effective treatment for TMNG and TA. Patients' characteristics that favor treatment with RAI include advanced age of patients, significant comorbidities, small goiters, adequate RAIU (>25%) as measured by thyroid uptake scans, prior surgery in the anterior neck, contraindications to surgery, and lack of access to a high-volume surgeon. Nygaard and colleagues reported a 52% rate of euthyroidism after a single ^{131}I treatment for TMNG, with an associated reduction in goiter volume by 40% at 24 months [35]. For TA, Nygaard et al. noted that 75% of patients were no longer hyperthyroid after their first RAI treatment, and that nodule volume showed a median reduction of 35% by 3 months and 45% by 24 months [36]. As demonstrated by Holm et al., hypothyroidism is the main side effect of RAI, with a higher incidence in patients who require more than one treatment to eliminate the hyperthyroid state [30].

Thyroid Surgery

Thyroid surgery should be considered if a patient has hyperthyroidism refractory to medical management, symptoms or signs of compression from goiter, coexisting hyperparathyroidism requiring surgery, large goiter, substernal or retrosternal goiter, insufficient RAIU (<25%), contraindications to RAI, thyroid nodule biopsy that is indeterminate or suspicious for thyroid cancer, or need for rapid correction of the thyrotoxic state [37]. Surgery for hyperthyroidism is advantageous because treatment is rapid, avoids the possible long-term risks of RAI and antithyroid medications, and it provides tissue for histologic examination. Risk of thyroid cancer in TMNG has been estimated to be 3%, although more recent data found an elevated risk of 21% [38, 39].

The operative complication rate is low when surgery is performed by high-volume thyroid surgeons [40]. In a recent cost-effectiveness analysis, surgery was more cost-effective than RAI unless patients had significant comorbidities that increased surgical mortality [41]. Near-total or total

thyroidectomy should be performed for Graves' disease and TMNG, since subtotal thyroidectomy is associated with an attendant risk of persistent or recurrent disease. Ipsilateral thyroid lobectomy, not subtotal thyroid lobectomy or nodulectomy, is indicated for toxic adenomas [42, 43]. Hypothyroidism should be anticipated following near-total or total thyroidectomy [24, 41]. Following surgery, antithyroid medications should be stopped and beta-blockers weaned appropriately. Thyroid hormone replacement should be started at a dose appropriate for the patient's weight, with thyroid function levels monitored every 1–2 months until stable, and then at least annually. In the immediate postoperative period, serum calcium levels should be measured at 6 and 12 h after surgery, and oral calcium and vitamin D supplementation (rocaltrol) can be administered to reduce the likelihood of developing symptomatic hypocalcemia requiring readmission [44].

In the elderly, thyroidectomy has been shown to be associated with worse clinical and economic outcomes than in younger cohorts, as measured by length of hospital stay, mean total costs, immediate perioperative mortality, discharge status, and clinical complications (Table 34.7) [45]. Using the Charlson Comorbidity Index, the elderly (aged 65–79 years) and superelderly (aged >80 years) were stratified into healthy (none to two comorbidities) and sick (three or more comorbidities) subgroups. Their outcomes have been examined based on whether the procedure was performed by low-volume (1–29 thyroidectomies/year) versus high-volume (>30 thyroidectomies/year) surgeons. More experienced surgeons had better outcomes than their less experienced colleagues

(Fig. 34.3). A separate population-level study provided compelling evidence for a significant association between increased surgeon volume and improved patients' outcomes following surgical procedures for both benign and malignant thyroid disease [46]. The lowest-volume surgeons (1–9 thyroidectomies/year) operated on a substantially greater share of elderly patients, who, in turn, had less access to urban hospitals and teaching institutions [45]. For this older population, the surgical risks and benefits must be carefully weighed.

Nodules

Epidemiology

Elderly patients frequently harbor thyroid nodules, and the incidence of thyroid nodules increases with age. Solitary palpable nodules occur in 4–7% of individuals and are approximately four times more prevalent in women than in men [47]. High-resolution ultrasound can detect thyroid nodules in 19–67% of randomly selected individuals, with higher frequencies in women and the elderly [48]. Exposure to radiation, particularly during childhood, is associated with an increased prevalence of thyroid nodules and papillary thyroid cancer. Iodine deficiency is associated with elevated risk of follicular thyroid cancer. Rapid growth, pain, and hoarseness are concerning for malignancy. Other risk factors for thyroid cancer include male gender, familial polyposis, Gardner's syndrome, Cowden's syndrome, familial papillary or medullary

thyroid cancer, and multiple endocrine neoplasia (MEN) IIA or IIB syndrome. The clinical importance of thyroid nodules rests with the need to exclude thyroid cancer, which occurs in 5–10% of patients with thyroid nodules [47, 48].

Clinical and Diagnostic Evaluation

Following the discovery of a solitary thyroid nodule, subsequent management depends on the knowledge of a cost-effective workup. Most patients with a solitary thyroid nodule have a benign lesion; however, thyroid cancer is a consideration in all patients. Deciding between surveillance and nonoperative management or surgical therapy relies on careful analysis of the presentation and assessment with imaging modalities such as dedicated neck ultrasound and thyroid uptake scan, along with cytologic diagnosis provided by FNA biopsy (Fig. 34.4) [49].

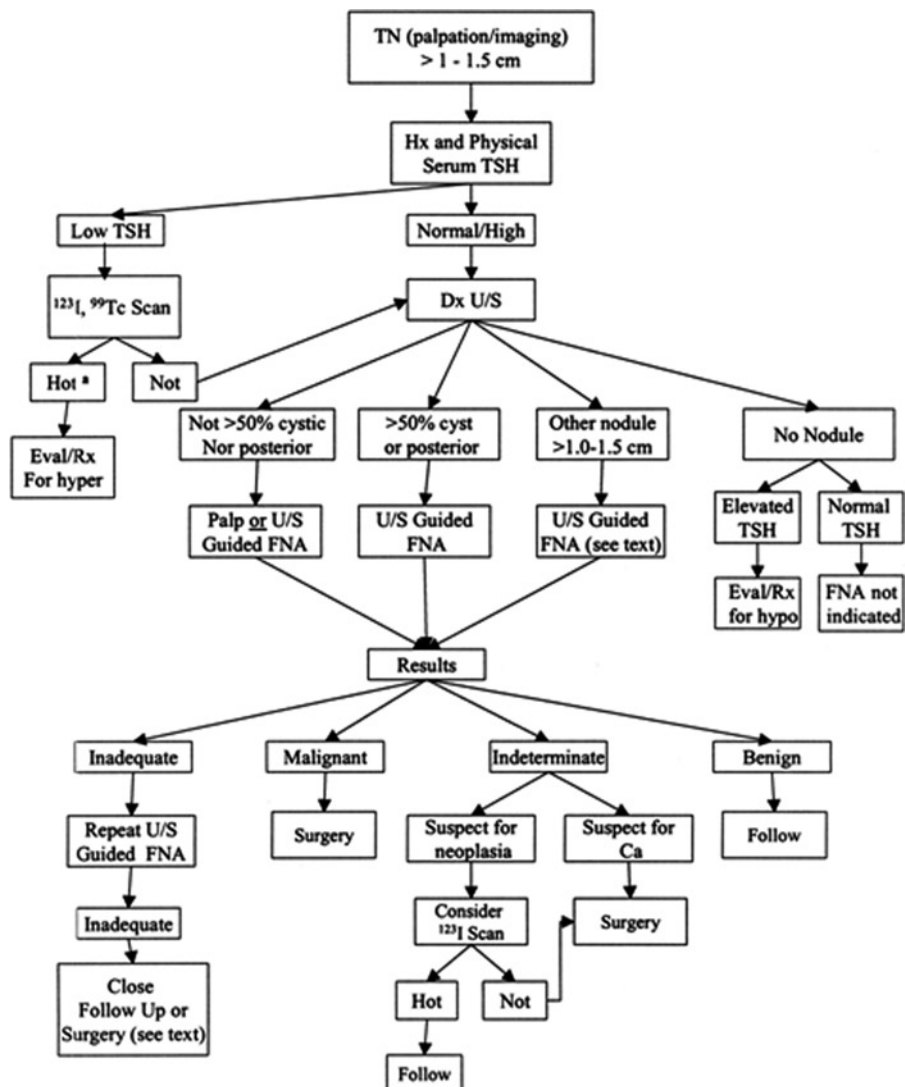

FIGURE 34.4 Algorithm for the evaluation of patients with one or more nodules (reprinted with permission from [5]).

The circumstances surrounding the onset and detection of the nodule and subsequent growth roughly correlate with malignant potential. Incidental subcentimeter nodules, identified during imaging procedures, have a very low probability of malignancy [50]. Slow growth over months to years can be seen with differentiated thyroid carcinomas or benign lesions. Rapid growth over days to weeks most commonly occurs with cyst formation in a goiter or hemorrhage into a preexisting cyst or nodule, but may rarely represent anaplastic thyroid carcinoma or primary thyroid lymphoma. Rapid onset of pain in a nodule often indicates hemorrhage into a goiter or benign adenoma. Slow onset of pain or hoarseness associated with a thyroid nodule is concerning for malignancy. Symptoms of hyperthyroidism are associated with an autonomous nodule (TA or “hot nodule”) or TMNG.

With the discovery of a thyroid nodule, a complete history and physical examination focusing on the thyroid gland and adjacent cervical lymph nodes should be performed. Risk factors for thyroid cancer are a history of head and neck irradiation in childhood or adolescence (papillary thyroid cancer), family history of thyroid cancer in a first-degree relative (familial papillary or medullary thyroid cancer, MEN IIA or IIB), and total body irradiation for bone marrow transplantation. Physical examination findings suggestive of malignancy include vocal cord paresis or paralysis, fixation of the nodule to surrounding tissues, or cervical lymphadenopathy [50].

In general, use of a complete blood count or standard electrolyte evaluation is unhelpful in the evaluation of a patient with a thyroid nodule. Thyroid function tests, including measurement of T_3 , T_4 , and TSH levels, should be employed to identify patients with hyper- or hypothyroidism. In 2006, the American Thyroid Association (ATA) Guidelines Taskforce recommended that if serum TSH is subnormal for nodules greater than 1–1.5 cm in diameter, then a radionuclide thyroid scan should be performed to determine whether the nodule is functioning with tracer uptake greater than the surrounding normal thyroid tissue (“hot”), isofunctioning (“warm”), or nonfunctioning with tracer uptake less than the surrounding thyroid (“cold”) (Fig. 34.5). In general, functional nodules rarely harbor malignancy [50]. However, a large series has shown that 16% of patients with cold nodules and 4% of patient with hot nodules had thyroid cancer documented by surgical resection [51]. It may be that the most useful current application for radionuclide scanning is in the setting of the workup for Graves’ disease.

Based on the ATA Guidelines, the finding of a nodule that is 1–1.5 cm in size warrants consideration of ultrasound and biopsy. An exception can be made for an elderly patient with a growing hot nodule. The likelihood of a hot nodule causing clinical hyperthyroidism over time is a function of its size. If there is evidence of autonomous function, an elderly patient with a large nodule should be considered for either RAI or surgery to prevent the development of atrial fibrillation or other cardiac complications prevalent in this population [10, 41].

FIGURE 34.5 ^{123}I thyroid scintigraphy (thyroid “uptake” scans).

FIGURE 34.6 Transverse ultrasound image showing multifocal papillary thyroid carcinoma.

Ultrasonography of the thyroid is used as the initial imaging modality of a palpable nodule. It is helpful in determining volume and size, number of nodules, whether nodules are solid or cystic, and (with serial ultrasonography) whether there is interval growth. Use of ultrasound has expanded into the office setting and also is available for intraoperative evaluation. It is highly operator-dependent. Ultrasound cannot distinguish between benign and malignant pathologies [52]. Thyroid cancers are hypoechoic in almost 80% of cases; in 20% of cases, they appear as inhomogeneous lesions with solid hypoechoic and cystic changes. However, up to 1% of all carcinomas show a homogeneously hyperechoic echotexture. Papillary thyroid carcinomas often contain microcalcifications (Fig. 34.6), but these also can be seen within benign hyperplastic or regressive nodules [53, 54].

Subclinical, subcentimeter nodules in patients without personal or familial risk factors should undergo size assessment by ultrasound examination and follow-up studies at 6 and 12 months. FNA should be performed for nodules that are 1–1.5 cm in size, smaller nodules with irregular edges or rapid size progression, and in patients with risk factors for thyroid malignancy [55]. Ultrasound-guided FNA is the most accurate and cost-effective method for evaluating thyroid nodules and suspicious cervical lymph nodes. It can be readily performed by experienced clinicians in the outpatient setting. With the patient in a supine position and the neck extended, the skin overlying the nodule is cleansed. Infiltration of a local anesthetic agent is optional. A 23- to 25-gauge needle is inserted into the nodule. Ultrasound-guided FNA biopsy of a thyroid nodule has certain advantages, including the ability to biopsy small, nonpalpable nodules and to biopsy the solid component of a thyroid cyst. While maintaining gentle suction on the syringe, the needle is moved forward and backward through the nodule to draw tissue into the needle. Suction is released, and the needle is withdrawn. The aspirated fluid is spread on a microscope slide and air-dried or fixed according to the preferences of the examining cytopathologist [56, 57].

Assessment of FNA-acquired tissue by an experienced thyroid cytologist can identify reliably the characteristics of particular processes. The features of papillary thyroid carcinoma, such as nuclear grooves, intranuclear cytoplasmic inclusions, psammoma bodies, fine powdery chromatin, and papillary formations, may be seen. Bland follicular cells, mature lymphocytes, and hemosiderin-laden macrophages are typical of nodular goiter, Hashimoto's thyroiditis, or cystic degeneration of a benign nodule.

Traditionally, FNA biopsy results are divided into four categories: nondiagnostic, benign, indeterminate or suspicious for neoplasm, and malignant. Nondiagnostic aspirates are due to insufficient sampling and typically contain few follicular cells and scant colloid. Such results should prompt a repeat FNA biopsy [56]. If a nodule is benign on cytology, additional diagnostic studies or treatment are not routinely required. Indeterminate or suspicious cytology can be found in 15–30% of FNA specimens [37]. Follicular and Hürthle cell neoplasms fall into this category because malignancy is determined by histologic evidence of vascular or capsular invasion that only can be determined on histologic analysis. Specific molecular markers have been evaluated to improve diagnostic accuracy of cytology in the setting of these lesions. Recent ATA Guidelines do not advocate routine use of these markers; instead, ipsilateral thyroid lobectomy, or near-total or total thyroidectomy (if there are multiple or bilateral nodules) is recommended [50]. Finally, aspirates of malignant nodules have unequivocal cytopathologic features of malignancy. These specimens tend to be highly cellular and exhibit typical architectural and cytologic features of primary thyroid carcinomas (papillary, medullary, or anaplastic),

lymphomas (primary or secondary), or metastatic tumors. Approximately 5% of aspirates fall into this category [58].

In the elderly population, primary thyroid lymphoma and anaplastic thyroid carcinoma are more common and present typically with a history of rapid nodule growth, often associated with subjective respiratory compromise and stridor. Prompt differential diagnosis is critical, as treatment options vary. Surgery, radiotherapy, and/or chemotherapy can be beneficial in the setting of primary thyroid lymphoma, while the treatment of anaplastic thyroid cancer is poorly effective and includes radiotherapy, palliative debulking, tracheostomy, and/or feeding tube placement.

Treatment

Patients with benign FNA results in the proper clinical setting should be followed-up periodically with focused physical examinations, as there is a false-negative rate of up to 5% with FNA [59]. Consideration should be given to ultrasound follow-up evaluation of nodule size and contour, and repeat FNA should be performed if the nodule increases in size or develops suspicious characteristics by ultrasound appearance or physical examination.

In the past, patients with benign nodules often were treated with thyrotropin-suppressive therapy with levothyroxine, which was thought to shrink some lesions and prevent enlargement of others. However, several studies indicate that only 20% of cytologically benign thyroid nodules undergo significant shrinkage with this therapy, and that 40–50% of these nodules shrink or disappear spontaneously. This may explain the apparent effectiveness of suppressive therapy reported in many uncontrolled clinical trials. Approximately 20% of cytologically benign thyroid nodules not treated with thyroid suppression enlarge over time, but only 5% of these nodules harbor malignancy [60, 61]. Given the potential long-term skeletal and cardiac effects of thyroid hormone, permanent suppressive therapy of presumed benign nodules is probably unwise in elderly women [10]. Furthermore, current ATA Guidelines do not recommend routine suppressive therapy of benign thyroid nodules [50].

Indications for surgical intervention include FNA findings of thyroid malignancy, suspicious for malignancy, or inconclusive neoplastic lesion; nodules with progressive growth in size; and, multiple thyroid nodules in the setting of prior ionizing radiation exposure [62]. In addition to resolving questions regarding malignancy, surgery can alleviate symptoms related to local mass effect on the upper aerodigestive tract. Patients can have dysphagia, chronic cough, or in the case of a substernal goiter, difficulty breathing. Substernal goiters are more common in the elderly [63, 64]. Often, elderly patients with long-standing goiter and respiratory complaints are diagnosed with asthma or chronic obstructive

FIGURE 34.7 Computed tomography image of goiter with extensive substernal component.

pulmonary disease when the extent of airway compromise caused by the goiter is unrecognized. Routine chest radiograph, CT scan, or MRI can determine the extent of the goiter and status of the patient's airway (Fig. 34.7). In most cases, substernal goiters can be removed through a cervical Kocher incision, even in reoperative circumstances [63–65].

Neoplasia

Epidemiology

Thyroid cancer represents less than 1% of all malignancies in the USA, occurring in approximately 40 per one million people per year [1]. Six deaths per one million people occur annually. While the incidence of thyroid cancer in the USA more than doubled over the past 30 years, almost 90% of this increase was due to the diagnosis of differentiated thyroid cancers [4]. Ninety percent of thyroid malignancies are categorized as well-differentiated tumors arising from a follicular cell origin. These include papillary thyroid cancer, follicular thyroid cancer, and Hürthle cell cancer. Medullary thyroid cancer, which arises from thyroid parafollicular or C cells, accounts for about 6% of thyroid cancers, of which 20–30% are inherited in the form of familial medullary thyroid cancer or MEN types IIA and IIB. Anaplastic thyroid cancer, also derived from thyroid follicular cells, is an aggressive malignancy and is responsible for less than 1% of thyroid cancers, and 600 new cases per year. Approximately 1% of thyroid malignancies are primary thyroid lymphoma,

usually of the non-Hodgkin's B-cell type [66]. Metastatic disease to the thyroid is rare and most commonly originates from renal cell carcinomas, breast cancers, and lung cancers. Other tumors that have been shown to metastasize to the thyroid include melanoma and those from esophagus, stomach, pancreas, colon, rectum, uterus, and larynx [67, 68].

Clinical and Diagnostic Evaluation

Evaluation of a patient for thyroid cancer should begin with a thorough history and physical examination. This should be followed by ultrasonography with FNA, and occasionally, CT (usually without intravenous contrast in case it is a differentiated thyroid cancer that will necessitate adjuvant RAI therapy) or MRI. In addition to thyroid function tests, patients with medullary thyroid cancer require preoperative evaluation of calcitonin, carcinoembryonic antigen (CEA), and catecholamine levels (24-h urine measurement of epinephrine, norepinephrine, metanephrine, normetanephrine, vanillylmandelic acid, and dopamine levels), particularly if there is suspicion of MEN IIA or IIB syndrome. In addition, consideration should be given to genetic screening with a serum *RET* (rearranged during transfection) proto-oncogene screen for all patients with medullary thyroid cancer.

Papillary thyroid cancer is the most common form, representing 80% of thyroid cancers. Prognostically, it is the most favorable. This tumor tends to exhibit intra- and extraglandular lymphatic spread; unlike other malignancies, presence of lymphatic metastases generally does not adversely influence prognosis, especially in young patients under age 45 years. Recognized variants of papillary carcinoma include encapsulated, follicular, tall cell, columnar cell, clear cell, and diffuse sclerosing carcinomas. Follicular thyroid cancer is more aggressive. Malignant lesions exhibit vascular or capsular invasion, and they spread hematogeneously to lung and bone. Like follicular thyroid cancer, Hürthle cell cancer, an oncocytic tumor, is considered malignant if there is evidence of vascular or capsular invasion. Although considered well-differentiated, Hürthle cell carcinoma holds a significantly worse prognosis than its papillary or follicular counterparts, in part because only a minority of tumors demonstrate iodine avidity. While the mean age at presentation is 30–40 years for papillary carcinoma, mean age at presentation for follicular thyroid cancer is 50 years, and for Hürthle cell carcinoma, 60 years [69, 70].

Medullary thyroid cancer arises from the calcitonin-secreting parafollicular or C-cells, which are derived from neural crest cells during embryologic development. Sporadic medullary thyroid cancer represents 70% of all cases; it tends to be unilateral and occurs after 30 years of age. Inherited medullary thyroid cancer accounts for 20–30% of all cases; it is almost always bilateral, associated with C-cell hyperplasia, and usually occurs before 30 years of age. Familial medullary thyroid

cancer can occur in the absence of associated endocrinopathy or as part of the MEN II syndromes. The pathologic features of medullary thyroid cancer include the presence of amyloid, a classic “salt-and-pepper” appearance of the cells, C-cell hyperplasia, and positive immunohistochemical staining for calcitonin and CEA. Patients present with a thyroid mass associated with cervical lymphadenopathy in up to 20% of cases. Symptoms are secondary to mass effect or to hypercalcitonism, as manifested by diarrhea and flushing. Hematogenous metastases to the liver, lung, and bones occur with disease progression. Prognosis varies with extent of disease. Sporadic and MEN-II-associated medullary thyroid tumors are more aggressive, and they carry a worse prognosis than MEN IIA or familial forms of the disease [71].

With the reduction of iodine-deficiency-associated goiters in the USA, the incidence of anaplastic or undifferentiated carcinoma has decreased to less than 1% of thyroid cancers. It usually arises in a well-differentiated cancer and in patients older than 60 years. Patients may detail a history of rapid enlargement of a neck mass in conjunction with pain, hoarseness, dyspnea, and dysphagia. Physical examination often reveals a firm, fixed thyroid mass with palpable cervical lymph node metastases. On FNA, spindle cells, small cells, or giant cells suggest the diagnosis. In many cases, additional pathologic material will be required to obtain a histologic diagnosis. While anaplastic thyroid cancer is rare, it accounts for more than half of the 1,200 deaths attributed to thyroid cancer annually in the USA [72]. Given the overall aggressiveness of the disease as well as its late clinical presentation, prognosis is extremely poor, with a 90% mortality within a mean interval of 9 weeks [73, 74].

Primary thyroid lymphoma is usually of the non-Hodgkin's B-cell type. It tends to occur in elderly women who present with a rapidly growing, often painful, thyroid mass with compressive symptoms. The overall 5-year survival for lymphoma of the thyroid is 70%. Older age, single marital status, advanced stage (stages II–IV), and histologic subtype (large B-cell, follicular, or other non-Hodgkin's) are associated with worse survival [75]. Primary squamous cell carcinoma and metastatic disease is rare. The diagnosis is most often confirmed by FNA and rarely requires surgical intervention [73].

A number of clinical scoring systems have been developed to assess prognosis of differentiated thyroid cancer. These include AGES (age, grade, extent, size), AMES (age, metastasis, extent, size), and MACIS (metastasis, age, completeness of resection, invasion, size) [76, 77]. For well-differentiated tumors, patients younger than 20 years, males older than 40 years, and females older than 50 years with cancers greater than 4 cm that have extended through the thyroid capsule and who have distant metastases are at higher risk of dying from the disease. In contrast, patients between ages 20 and 40 years with a tumor less than 4 cm confined to the thyroid are at low risk and have an excellent prognosis. The TMN staging system adopted by the American Joint Committee on Cancer

(AJCC), as well as the International Union Against Cancer (UICC), is universally accepted and is required by tumor boards for standardized reporting (Table 34.8) [50].

Treatment

The goals of initial therapy of differentiated thyroid cancer are to (1) remove the primary tumor, disease beyond the thyroid capsule, and involved cervical lymph nodes; (2) permit accurate staging of the disease; (3) minimize treatment-related morbidity; (4) facilitate postoperative treatment with RAI if appropriate; (5) allow for accurate long-term surveillance for recurrence; and (6) minimize risk of locoregional disease recurrence and metastatic spread [50].

Successful thyroid surgery requires an appreciation of the normal anatomic relations of the thyroid and parathyroids, the recurrent and superior laryngeal nerves, and the inferior thyroid arteries, as well as their common anatomic variations. Lo Gerfo and colleagues have shown that bilateral neck exploration under regional anesthesia can be performed safely in patients with thyroid disease [78, 79]. However, most surgeons prefer general endotracheal anesthesia. The relatively short duration of the procedure and lack of significant fluid shifts and hemodynamic changes allows it to be well-tolerated, even in older patients.

According to the ATA Guidelines, near-total or total thyroidectomy are acceptable operations for papillary thyroid cancer. They are followed by a 10-year survival rate in excess of 90%. Subtotal or partial lobectomy (“nodulectomy”) is contraindicated. Total thyroidectomy is preferred over other operations because of the high incidence of multifocal disease, a clinical recurrence rate of 7% in the contralateral lobe if it is spared, and the ease of assessment for recurrence by serum thyroglobulin assay or radioiodine scan during follow-up exams. In addition, total thyroidectomy increases the efficacy of RAI therapy. Routine central compartment (level VI) neck dissection continues to be an area of great controversy. Although there are ample data that micrometastases to this level are not infrequent, central lymphadenectomy comes with increased attendant risk of recurrent laryngeal nerve injury and hypoparathyroidism. If there is palpable, biopsy-proven, or grossly apparent metastasis at the time of surgery, lymphadenectomy should be performed. However, if these conditions are not present and if postoperative RAI ablation is planned, dissection of nonpalpable central lymph nodes is debatable [80, 81]. A modified radical neck dissection (levels II–V), preserving the sternocleidomastoid muscle, spinal accessory nerve, and internal jugular vein, usually is indicated for patients with clinically palpable or biopsy-proven cervical adenopathy [82].

Patients with an FNA-diagnosis of follicular or Hürthle cell neoplasm should undergo ipsilateral thyroid lobectomy and isthmusectomy because approximately 20% of these

TABLE 34.8 American Joint Committee on Cancer (AJCC) pathologic-tumor-node metastasis (pTNM) system**Definition**

Tx	Primary tumor cannot be assessed			
T0	No evidence of primary tumor			
T1	Tumor diameter 2 cm or less limited to the thyroid			
T1a	Tumor diameter 1 cm or less limited to the thyroid			
T1b	Tumor diameter 1–2 cm limited to the thyroid			
T2	Primary tumor diameter >2–4 cm			
T3	Primary tumor diameter >4 cm limited to thyroid or with minimal extrathyroidal extension			
T4a	Tumor of any size extending beyond thyroid capsule to invade soft tissues, larynx, trachea, esophagus, recurrent laryngeal nerve (moderately advanced)			
T4b	Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels (very advanced)			
Nx	Regional lymph nodes cannot be assessed			
N0	No regional lymph node metastasis			
N1	Regional lymph node metastasis			
N1a	Metastases to level VI (pretracheal, paratracheal, prelaryngeal/Delphian lymph nodes)			
N1b	Metastases to unilateral, bilateral, contralateral cervical or superior mediastinal lymph nodes			
Mx	Distant metastases not assessed			
M0	No distant metastases			
M1	Distant metastases

lesions will prove to be carcinomas. The diagnosis of carcinoma is confirmed by the finding of capsular and vascular invasion on permanent histology. Detection of macroinvasion necessitates completion of thyroidectomy. Indications for total thyroidectomy include obvious extension of the lesion through the thyroid capsule, lesions greater than 4 cm (50–80% prove to be malignant), and contralateral nodularity or pathology. Follicular carcinoma is associated with a 10-year survival of 85% and 20-year survival of 70% [70]. Like papillary and follicular malignancies, Hürthle cell carcinomas produce thyroglobulin, a useful marker for postoperative surveillance. However, Hürthle cells are not iodine-avid; therefore, surgical resection is the mainstay of treatment.

In patients with papillary or follicular thyroid cancer, postoperative ablation with ^{131}I is used more frequently to

eliminate residual thyroid tissue in order to decrease the risk of locoregional recurrence as well as to facilitate long-term surveillance with radioiodine scans. Several retrospective studies have demonstrated a significant reduction in the rates of disease recurrence and disease-associated mortality [70, 83]. In order to effectively administer postoperative RAI, the patient must be sufficiently hypothyroid as shown by elevated serum TSH levels. Levothyroxine is withheld or withdrawn for 4–6 weeks to maximize thyrotropin stimulation of the remaining thyroid tissue. The resulting hypothyroidism is tolerated poorly by some patients, and it may be attenuated by administration of liothyronine sodium to ensure a shorter duration of hypothyroidism. Recently, administration of recombinant human thyrotropin (rhTSH) has been used in lieu of traditional thyroid hormone withdrawal.

CASE STUDY RESOLUTION

JK's medical and surgical teams discussed the risks and benefits of total thyroidectomy with the patient, and the decision was made to proceed with surgery given the apparent aggressive nature of her cancer. Given her subjective hoarseness, indirect laryngoscopy was performed, and her vocal cord function was deemed to be intact; she had mild reflux. Appropriate medical and cardiologic clearance was obtained. The patient met with anesthesiology preoperatively. Her warfarin was stopped 5 days prior to surgery, as was her vitamin supplement. Total thyroidectomy with en bloc resection of the right strap muscle was performed, along with a right central lymph node

dissection. The patient did well postoperatively; she had no evidence for change in voice or hypoparathyroidism. Her warfarin was restarted on postoperative day 1, and she was discharged home that day with follow-up with her cardiologist later in the week. Her final pathology revealed multifocal papillary thyroid cancer. The largest focus measured 4.1 cm in the right lobe, and an additional 5 mm focus was identified in the contralateral lobe. Lymphovascular invasion was seen, and there was extension of tumor into soft tissue, but surgical margins were negative. Three of ten lymph nodes were positive for metastatic disease, giving her an AJCC pT4aN1aMx, or stage IVA, papillary thyroid cancer. She met with endocrinology regarding adjuvant RAI therapy.

Successful remnant ablation with ^{131}I was equivalent after thyroxine withdrawal compared to rhTSH stimulation when the thyroxine therapy was stopped 1 day prior to the rhTSH injections and restarted the day following RAI [84–86].

Treatment for medullary thyroid cancer generally includes total thyroidectomy and central lymph node dissection. An ipsilateral or bilateral modified radical neck dissection is performed for lateral cervical lymph node disease. Tumor debulking may be helpful in alleviating diarrhea and flushing. Nutmeg oil, a combination of atropine sulfate and diphenoxylate hydrochloride, or subcutaneous somatostatin analogue has offered some relief from symptoms of metastatic disease [71]. Postoperatively, calcitonin remains a highly sensitive tumor marker and may remain elevated in patients who present with bulky disease. Preoperative basal calcitonin levels can individualize the extent of surgery and postoperative follow-up intervals. On multivariate analysis, preoperative basal serum calcitonin levels >500 pg/ml best predicted failure to achieve biochemical remission, followed by nodal metastasis and need for reoperation. Patients with nodal or distant metastases did not achieve biochemical remission when their preoperative basal calcitonin levels exceeded 3,000 pg/ml. Nodal metastasis emerged at basal calcitonin levels of 10–40 pg/ml, while distant metastases and extrathyroidal growth appeared with basal calcitonin levels of 150–400 pg/ml [87]. Despite this, some patients with medullary thyroid cancer survive for many years with minimal symptoms despite significant tumor burden. Chemotherapy is poorly effective in the management of locally advanced and metastatic medullary thyroid cancer, and the role of radiation therapy is questionable. The best results are achieved in familial medullary or MEN II kindreds where patients can be identified presymptomatically and appropriately treated [55, 71]. More recently, tyrosine kinase inhibitors have been shown to inhibit *RET* tyrosine

kinase activity. Clinical studies are underway, but only preliminary results have been published [88, 89].

Anaplastic thyroid cancer most often is advanced at presentation, and it usually presents in the 6–7th decades of life. It is almost always unencapsulated and invades surrounding structures. Cervical lymphadenopathy and pulmonary metastases are common. It does not concentrate iodine or express thyroglobulin [90]. Although there is no satisfactory treatment for anaplastic cancer, local control can be attempted with palliative surgery, chemotherapy, or radiotherapy. Tumor debulking, tracheostomy, and feeding gastrostomy may be required for palliation [91]. In the rare instance of early anaplastic carcinoma localized to the thyroid, total thyroidectomy has resulted in long-term survival [92].

Primary non-Hodgkin's lymphoma of the thyroid is most common in elderly women, occurring most often in the background of autoimmune thyroid disease. Primary thyroid lymphoma usually is not a surgical disease, although surgeons often assist by obtaining adequate tissue to establish a diagnosis and determine tumor markers. Use of multimodality chemotherapy, particularly with anthracycline agents, and external radiotherapy results in dramatic tumor shrinkage and rapid resolution of airway compromise. The overall 5-year survival is approximately 70%, depending on stage and histologic type [71, 75, 93].

Conclusion

Thyroid disease is common in the elderly. In this population, the clinical manifestation of thyroid dysfunction can be subtle, often hidden by a background of coexistent disease. Hypo- and hyperthyroidism often are subclinical, and therapeutic decisions may be dictated by patients' preference and overall health

status. The incidence of thyroid nodules increases with age, as does the risk of thyroid malignancy and the aggressiveness of the thyroid tumor. Surgery is the mainstay of treatment for thyroid cancer. Quality-of-life issues related to voice, swallowing, and calcium metabolism are especially salient in elderly patients. Thyroid surgery in this population is associated with increased attendant risk, but it can be performed safely, especially in the hands of high-volume thyroid surgeons. It is imperative that internists, geriatricians, endocrinologists, and thyroid surgeons work together as an interdisciplinary team to formulate and tailor treatment strategies.

Chapter 35

Parathyroid Disease in the Elderly

Leslie S. Wu, Sanziana A. Roman, and Robert Udelsman

CASE STUDY

An 82-year-old woman was brought to the Emergency Department with a 5-day history of worsening lethargy and confusion. From prior hospital records, her past medical history was notable for two episodes of nephrolithiasis, gastroesophageal reflux disease, and hypertension. Her medications included hydrochlorothiazide, metoprolol, omeprazole, and aspirin.

Physical examination revealed a frail-appearing woman, who was arousable to voice, and oriented only to person. She was afebrile and normotensive, but mildly tachycardic with a heart rate of 100 beats per minute. Neurologic exam was nonfocal. The remainder of her

examination was significant only for poor skin turgor and dry mucous membranes.

Laboratory studies were notable for a normal white blood cell count, mild hemoconcentration, blood urea nitrogen (BUN) 25 mg/dL, serum creatinine 1.3 mg/dL, serum calcium 14.7 mg/dL, and albumin 4.3 g/dL. Urinalysis was negative.

The patient was admitted to the hospital with hypercalcemia. She was hydrated appropriately with intravenous crystalloid fluids, with subsequent improvement of her mental status and calcium level. Additional laboratory evaluation was obtained, revealing an intact parathyroid hormone (iPTH) level of 200 pg/ml. The patient was diagnosed with primary hyperparathyroidism.

Introduction

The primary function of the parathyroid glands is to maintain calcium homeostasis through the secretion of parathyroid hormone (PTH). This hormone is regulated by serum calcium through calcium-sensing receptors (CaSRs) on the parathyroid cell surface. In turn, most peripheral tissues, primarily kidney and bone, have PTH receptors which can affect varying functions. In the past, disturbances in this system were difficult to recognize until the development of clinically significant disease. With the development of better biochemical assays for serum PTH and calcium levels, subclinical derangements can be diagnosed before patients become symptomatic. The management of patients with the broad spectrum of metabolic calcium disturbances remains controversial.

Mineral Homeostasis

Plasma calcium exists in three phases: protein-bound, ionized, and complexed. Normally, approximately 1 g of inorganic calcium is absorbed daily in the proximal small intestine. About 45% of total blood calcium is protein-bound, predominantly to albumin, but also to globulins. A similar fraction is ionized. The rest is complexed to organic ions such as citrate, phosphate, and bicarbonate. Calcium is in constant flux between the extracellular and intracellular spaces, in bone, and in renal glomerular filtrate, which is reabsorbed by the normal kidney.

The ionized fraction of serum calcium controls vital cellular functions, such as neuromuscular transmission, muscle contraction, and blood clotting. Precise maintenance of calcium concentration within a very narrow range in extracellular fluids is therefore critically important. The binding of calcium to albumin is pH-dependent, increasing with alkalosis, and decreasing with acidosis. Thus, if the ionized calcium is low, acidosis tends to protect an individual from manifesting the symptoms and signs of hypocalcemia; conversely, alkalosis predisposes a patient to symptomatic hypocalcemia.

FIGURE 35.1 Calcium metabolism.

The adult body contains approximately 700 g of phosphate, primarily located in the teeth and bones. Plasma levels of calcium and phosphate are inversely related, and the primary agents responsible for calcium metabolism are PTH, vitamin D, and calcitonin (see Fig. 35.1) [1].

Parathyroid Hormone (PTH)

The chief cells of the parathyroid gland constantly monitor ionized calcium concentrations through their cell surface CaSR, thus allowing the circulating level of PTH to change within seconds after an alteration in serum calcium [2]. PTH secretory rates are related to serum ionized calcium and 1,25-dihydroxyvitamin D by an inverse sigmoidal relationship. Low ionized calcium concentrations maximally stimulate secretion, while increases in calcium suppress the production and release of PTH. PTH secretion is exquisitely sensitive to very small alterations in the calcium concentration, which have substantial effects on the rate of hormone synthesis and release.

PTH is synthesized within the parathyroid gland as a 115-amino-acid precursor molecule (preproPTH) that is successively cleaved within the cell to form the mature 84-amino-acid PTH. This form of the hormone is packaged into

secretory granules and released into the circulation. Mature PTH is metabolized in the liver into the active N-terminal and inactive C-terminal fragments. The intact molecules and N-terminal fragments have half-lives of approximately 3–5 min, while the inactive C-terminal fragments have a half-life of hours. The C-terminal fragments are excreted by the kidneys, and usually accumulate to high levels in the serum of patients with renal failure.

PTH inhibits osteoblasts and stimulates osteoclasts. In the kidney, PTH causes a decrease in calcium clearance as well as increased renal excretion of phosphate by inhibiting its reabsorption in the tubules. In addition, PTH stimulates hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, which allows for enhanced calcium absorption in the proximal intestine [3].

Vitamin D

The sterol 1,25-dihydroxyvitamin D, or calcitriol, is an essential mediator of calcium homeostasis. Calcitriol synthesis begins with ultraviolet activation of 7-dehydrocholesterol in the skin, generating cholecalciferol (vitamin D). In the liver, vitamin D is readily hydroxylated to 25-hydroxyvitamin D₂,

which in turn is hydroxylated to the potent calcitriol. This final step occurs in the kidney and is tightly regulated by PTH. In turn, calcitriol has a regulatory effect on PTH, by exerting a physiologic inhibition of the parathyroid glands [4].

Calcitonin

Parafollicular, or C cells, of the thyroid gland secrete the peptide hormone calcitonin. Calcitonin interacts with receptors in kidney and bone. The primary function of calcitonin is to lower serum calcium, and this hormone is released rapidly in response to hypercalcemia. It inhibits osteoclastic bone resorption and quickly blocks the release of calcium and phosphate from bone. Ultimately, this effect, along with the inhibition of resorption, leads to a fall in serum calcium and phosphate [3]. The physiologic effect of calcitonin in humans, however, is very modest.

Hypercalcemia

The most common reason for the finding of hypercalcemia in an elderly patient, in the outpatient setting, is primary hyperparathyroidism (HPTH), while hypercalcemia in the inpatient population often is secondary to malignancies. Diagnosing the correct etiology requires careful clinical evaluation of patients, as well as serologic and biochemical testing (Table 35.1) [5].

After a thorough history and physical examination, laboratory measurements of fasting serum calcium, PTH, creatinine, and vitamin D levels should be performed to determine if the hypercalcemia is parathyroid-mediated (in which serum PTH levels are elevated inappropriately) or non-parathyroid-mediated (in which serum PTH levels are suppressed appropriately). Normally, functioning parathyroid cells abruptly cease PTH release when the surrounding extracellular fluid calcium concentration is elevated. Therefore, in cases in which hypercalcemia results from a non-parathyroid-mediated condition, serum PTH levels will be suppressed [6].

TABLE 35.1 Differential diagnosis of hypercalcemia

Parathyroid-mediated	Non-parathyroid-mediated
Primary hyperparathyroidism	Malignancy-associated hypercalcemia
Parathyroid adenoma (85%)	Local osteolytic hypercalcemia
Parathyroid hyperplasia (15%)	Humoral hypercalcemia of malignancy (PTHrP and calcitriol)
Parathyroid carcinoma (<1%)	Granulomatous disease (sarcoidosis and tuberculosis)
Secondary/tertiary hyperparathyroidism	Endocrinopathies (hyperthyroidism and adrenal insufficiency)
Familial hypocalciuric hypocalcemia	Drugs (thiazides, vitamin D and calcium)
Lithium therapy	Immobilization

Source: Modified and reproduced from [1]

Non-Parathyroid-Mediated Hypercalcemia

This category includes conditions in which patients have hypercalcemia and serum PTH levels that are suppressed appropriately; the parathyroid cells perceive excess extracellular calcium concentrations, and markedly reduce their hormonal release. Cancer is the most frequently diagnosed etiology of non-PTH-mediated hypercalcemia, particularly in the hospitalized population. This malignancy-associated hypercalcemia is classified into two primary forms, osteolytic and humoral.

The second form of malignancy-associated hypercalcemia is local osteolytic hypercalcemia, which occurs when a neoplasm directly invades the bony skeleton, resulting in localized destruction and calcium release. In contrast to malignant humoral hypercalcemia, local osteolytic hypercalcemia does not involve the elaboration of systemically active products. Rather, it appears to result from the production or local stimulation of bone-active cytokines as well as other osteoclast-activating factors. This form of pathologic hypercalcemia is most commonly associated with multiple myeloma; however, it has also been linked to adenocarcinoma of the breast and certain lymphomas [7].

Humoral hypercalcemia of malignancy results from the systemic effect of a circulating factor produced by the neoplasm. Most commonly, the factor involved is parathyroid hormone-related protein (PTHrP), a peptide that has been shown to recapitulate most of the metabolic effects of PTH, including stimulation of bone turnover and alteration in renal handling of both calcium and phosphate [7]. In humans, PTHrP serves as an important paracrine factor in many tissues, including skin, bone, breast, the central nervous system, and the vasculature. Neoplasms that elaborate PTHrP include squamous cell carcinomas (naso- and oro-pharynx, larynx, lung, esophagus, and cervix), adenocarcinoma of the breast and ovary, bladder transitional cell carcinoma, T-cell lymphomas, renal cell carcinoma, and carcinoid tumors. The other factor that may cause malignant humoral hypercalcemia is calcitriol, which is often associated with B-cell lymphomas [7, 8].

There are other benign, non-PTH-mediated causes of hypercalcemia encountered in the elderly. These include medications and supplements, such as thiazide diuretics and excess exogenous calcium, vitamin D, or vitamin A. Granulomatous diseases, such as sarcoidosis and tuberculosis, are associated with hypercalcemia through the direct production of calcitriol. In addition, several endocrinopathies are associated with hypercalcemia, including hyperthyroidism with augmented bone turnover, pheochromocytoma with PTHrP production, and adrenal insufficiency linked with decreased calcium clearance. Rarely, hypercalcemia may result from prolonged immobilization, particularly in settings in which bone turnover is already stimulated, such as recovery from fractures or surgery [3].

Parathyroid-Mediated Hypercalcemia

The differential diagnosis of parathyroid-mediated hypercalcemia includes HPTH, familial hypocalciuric hypocalcemia (FHH), and lithium therapy. The remainder of this chapter will focus primarily on the forms and treatment strategies of HPTH. However, FHH and lithium therapy briefly are discussed below, as the differences between these diagnoses are important.

FHH, also known as benign familial hypercalcemia, is an inherited autosomal dominant condition resulting from a deactivating mutation in the extracellular CaSR [9]. In this condition, the cell surface receptor is sub-normally activated by extracellular calcium. In the face of mild elevation of serum calcium, PTH levels are inappropriately normal or slightly elevated. However, urinary calcium excretion is reduced, due to the same defective CaSRs in the nephron, with subsequent increased urinary calcium reabsorption. Although FHH is classified as parathyroid-mediated, since PTH secretion is abnormal, it is a unique condition and distinct from the more common primary HPTH. Generally, it is diagnosed in younger patients with asymptomatic, mild hypercalcemia. The family history usually identifies affected relatives. It does not require surgical intervention, as parathyroidectomy will not cure the condition.

Chronic lithium therapy may increase serum calcium levels with inappropriately normal or mildly elevated PTH concentrations. Lithium appears to alter the sensitivity of the CaSR, thus increasing the set-point of extracellular calcium concentration. However, parathyroid adenomas and multigland hyperplasia have also been described in patients chronically treated with lithium [10]. Distinguishing those patients with drug-induced hypercalcemia from those with mild primary HPTH can be challenging.

Hyperparathyroidism

Hyperparathyroidism was first recognized during the 1920s and was thought to be a relatively uncommon condition, presenting usually as nephrolithiasis or as a complication of severe bony demineralization [5]. With the application of multiphasic blood testing revealing elevated serum calcium concentrations and the availability of accurate PTH determinations, HPTH now is recognized to be a more common disorder, particularly in the elderly population.

Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common form of HPTH and is the most frequent explanation for hypercalcemia

in the outpatient setting. Population-based estimates reveal an overall incidence of approximately 25 per 100,000 in the general population with about 50,000 new cases occurring annually. The peak incidence is in the fifth to sixth decade of life, with a female to male ratio of about 3:2. Some studies estimate the overall prevalence of HPTH in the elderly at 2–3%, with approximately 200 cases/100,000 population [11].

The most common clinical presentation is that of asymptomatic, or minimally symptomatic, mild hypercalcemia. Primary HPTH generally is caused by a benign, solitary parathyroid adenoma in 80–85% of patients. In about 5% of patients, two distinct adenomas (“double adenoma”) are found. Multigland parathyroid hyperplasia is present in 15–20%. In younger patients, this may be associated with familial syndromes, such as multiple endocrine neoplasia (MEN) types I and IIA. Patients with MEN-I have enlargement and hyperfunction of all parathyroid glands, whereas patients with MEN-IIA may have asymmetric parathyroid gland enlargement. The rare hyperparathyroidism-jaw tumor syndrome is another autosomal dominant inherited condition presenting with early-onset primary HPTH and fibro-osseous, cystic jaw neoplasms [12, 13]. Index cases of MEN syndromes are rare in the elderly patients, but certain mutations may manifest later in life, therefore in the appropriate clinical setting, MEN needs to be considered even in elderly patients.

Parathyroid carcinoma is a rare cause of primary HPTH, accounting for less than 1% of cases. In contrast to benign HPTH, it occurs equally in men and women. Patients with parathyroid carcinoma present most often in the fifth and sixth decades of life. Longstanding untreated primary HPTH may devolve into parathyroid carcinoma, which may then present in the elderly patients [14]. Although these tumors are slow-growing, they have a high propensity to recur locally, and recurrent disease is difficult to eradicate. Patients with recurrent and metastatic disease often suffer from severe, debilitating hypercalcemia, control of which may involve palliative surgical resection and the use of drugs, including bisphosphonates and calcimimetics, to lower the serum calcium level [15, 16].

Clinical and Diagnostic Evaluation

With the advent of routine serum calcium screening, the typical presentation of primary HPTH has changed from a severe, debilitating illness to a disease with subtle symptoms and physiologic derangements. Common signs include nephrolithiasis, nephrocalcinosis, osteopenia, and osteoporosis (Table 35.2) [17]. Hypertension is frequently present in patients with primary HPTH, and a variety of mechanisms have been proposed to explain this relationship. It appears to be most closely correlated with the degree of renal impairment seen in patients with hypercalcemia. However, one

TABLE 35.2 Symptoms and associated conditions in patients with primary hyperparathyroidism**Symptoms**

Weakness, exhaustion, and fatigue
 Bone pain, back pain, and joint pain
 Polyuria, nocturia, and polydipsia
 Loss of appetite, nausea, and dyspepsia
 Memory loss and depression

Associated conditions

Weight loss
 Bone fracture, joint swelling, and gout
 Nephrolithiasis, hematuria from passage of renal calculus
 Gastric ulcer, duodenal ulcer, and pancreatitis
 Hypertension

study found that parathyroidectomy led to a substantial fall in both systolic and diastolic pressures in 54% of hypertensive subjects that appeared to be unrelated to improvement in renal function [18]. Most endocrine specialists do not believe that curative surgery in primary HPTH is associated with a significant improvement in hypertension.

There are many subtle abnormalities associated with primary HPTH, including decreased cognitive function, depression, lethargy, myalgias, arthralgias, constipation, and urinary symptoms, such as increased thirst and urinary frequency. Petersen performed psychiatric examinations on 54 patients with primary HPT and detected mental disturbances in more than 50% [19, 20]. However, it is often difficult to prove that these nonspecific findings result from primary HPTH because they are common in the elderly. In a general population cohort study of over 4,000 individuals, Schram et al. found that serum calcium levels that were at the upper range of normal or frankly elevated were associated with faster decline in cognitive function, particularly for patients over the age of 75 years [21].

The diagnosis of primary HPT typically is made by biochemical evidence of an elevated serum calcium concentration, usually in conjunction with an elevated serum intact PTH. Approximately half of patients with primary HPTH have hypophosphatemia. However, in the presence of significant renal impairment, serum phosphate levels may be elevated. Because of the effect of PTH on bicarbonate excretion in the kidney, patients with primary HPTH often have a hyperchloremic metabolic acidosis [13]. Approximately 10–40% of HPTH patients have elevated levels of alkaline phosphatase, which indicates some degree of increased bone turnover. Although osteitis fibrosa cystica, the classic form of parathyroid bone disease, is rarely seen today, even patients with mild disease can be seen to have biochemical or histologic evidence of bone involvement. Dual-energy X-ray absorption (DEXA) scanning of the lumbar spine, hip, and forearm has become the standard method for assessing bone density to diagnose osteoporosis in the setting of primary HPTH [22–24].

**FIGURE 35.2** Parathyroid adenoma. Sagittal ultrasound shows a parathyroid adenoma (white arrows) behind the lower pole of the right thyroid lobe (black arrows).

Patients with FHH must be distinguished from those with primary HPTH. This can be done with a 24-h urinary calcium excretion study, which is uniformly low in the setting of FHH. In contrast, patients with primary HPTH have a normal or elevated 24-h urinary excretion of calcium [9]. Postmenopausal women often have hypercalciuria for several years after the onset of menopause from estrogen decrease, therefore increased urinary calcium levels in this population may not always be due to hyperparathyroidism.

Although rare, parathyroid carcinoma should be suspected in patients who demonstrate a rapid and sustained rise in both their serum calcium and PTH levels. A palpable neck mass sometimes may be appreciated [25, 26]. A parathyroid adenoma is rarely, if ever, palpable on physical examination. Rather, this neck mass is more likely to represent a thyroid nodule.

There have been extensive discussions regarding the use and availability of preoperative imaging studies in patients with primary HPT. In the past, patients who had not undergone previous surgical exploration did not require any radiographic localization studies other than finding an experienced parathyroid surgeon. However, the increased use of minimally invasive parathyroidectomy techniques has mandated preoperative imaging.

Imaging studies can be sorted into noninvasive and invasive techniques. The noninvasive studies include the following: nuclear medicine scans, such as methoxyisobutylisonitrile (sestamibi) studies, which can be combined with single photon emission computed tomography (SPECT) imaging; ultrasound (Fig. 35.2); computed tomography (CT) scans; and magnetic resonance imaging (MRI). The noninvasive

localization study of choice is a technetium (^{99m}Tc)-sestamibi scan with SPECT, which results in a three-dimensional reconstruction that can delineate the location of an enlarged parathyroid gland in 85% of cases (Fig. 35.3a, b).

Invasive techniques usually are reserved for re-operative cases, and include angiography and venous sampling for PTH gradients. Recently, the rapid PTH assay has been used in both the angiography suite as well as the operating room. It yields real-time feedback and has become invaluable in the development of minimally invasive techniques [27–29].

Most patients presenting with primary HPT are asymptomatic, or mildly, chronically ill with vague symptoms referable to the kidneys or the musculoskeleton. However, patients may become acutely and severely ill with acute hypercalcemia, or hyperparathyroid crisis. This disorder often can be seen in elderly patients, nursing home residents, or patients with cognitive deficits, such as dementia. Such patients often harbor mild to moderate hyperparathyroidism for years, but an inciting factor will cause acute worsening of the hypercalcemia. The most common etiology is simple dehydration from poor health, overuse of diuretic medications, gastroenteritis or viral illness. The onset is usually characterized by rapidly developing muscular weakness,

nausea and vomiting, weight loss, drowsiness, fatigue, and confusion. The serum calcium concentration almost always is remarkably elevated (16–20 mg/dL). The offending parathyroid gland is usually large. The genesis of the condition involves uncontrolled PTH secretion followed by hypercalcemia, polyuria, dehydration, and reduced renal function, which worsens the hypercalcemia [10].

The management of severe hypercalcemia incorporates four primary aims: to correct dehydration; to enhance renal excretion of calcium; to inhibit bone resorption; and to treat the underlying disorder. Although the definitive therapy is resection of the hyperfunctioning parathyroid gland, it is unsafe to proceed with operative exploration until the serum calcium concentration is lowered. Resuscitation with 0.9% normal saline is instituted to maintain urinary output above 100 ml/h, and subsequent diuresis with loop diuretics increases the renal excretion of sodium and calcium. In the elderly patients, care must be taken to assess their cardiac function, so as to avoid overhydration and fluid overload. If the serum calcium level remains elevated, other agents that can lower the serum calcium concentration should be administered. These agents include bisphosphonates, calcitonin, and cinacalcet [10]. Often, multidisciplinary care is needed for these complex patients.

Treatment

There has been considerable debate regarding the management of elderly patients with primary hyperparathyroidism. There is universal agreement that patients with clear symptoms and signs associated with hyperparathyroidism should undergo parathyroid surgery because parathyroidectomy is the only long-term effective treatment. However, controversy still exists about the management of patients with “asymptomatic” primary HPTH [30, 31]. Recent data suggest that these asymptomatic patients often have symptoms that are recognized in retrospect, once their HPTH has been cured. In addition, asymptomatic patients may suffer from neurocognitive deficits, depression, and anxiety, as well as progressive cardiovascular disease, and a suggestion of insulin resistance, which can result in premature death [32, 33].

In 1990 and 2002, the National Institutes of Health (NIH) convened consensus conferences to delineate the surgical indications in patients with both symptomatic and asymptomatic primary HPTH (Table 35.3) [34, 35]. In 2008, an international workshop on HPTH convened to review and update previous recommendations [36]. Guidelines also were created for the management of patients with asymptomatic primary HPTH who did not undergo surgery, including biannual serum calcium and annual serum creatinine measurements, as well as annual bone density measurements [35]. It has been suggested, however, that the NIH criteria for parathyroidectomy in asymptomatic patients are too limited and that all patients with primary HPTH should be referred for surgical therapy [37, 38].

There is no long-term effective pharmacologic treatment for primary HPTH. There are several pharmacologic agents that can transiently lower the serum calcium level (Table 35.4). These can limit further loss of bone by reducing the activation of new remodeling units in the skeleton. Estrogen replacement, salmon calcitonin, bisphosphonates, and more recently, calcimimetics (cinacalcet) have been used to treat

TABLE 35.3 Surgical indications in patients with primary hyperparathyroidism

All symptomatic patients, including those with significant bone, renal, gastrointestinal, or neuromuscular symptoms typical of primary hyperparathyroidism
<i>In otherwise asymptomatic patients:</i>
Elevation of serum calcium by 1 mg/dl or more above the normal range (i.e., >11.5 mg/dl in most laboratories)
Marked elevation of 24-h urine calcium excretion (e.g., >400 mg)
Decreased creatinine clearance (e.g., reduced by >30% compared with age-matched normal person)
Significant reduction in bone density of more than 2.5 standard deviations below peak bone mass at any measured site (i.e., <i>T</i> -score <2.5)
Consistent follow-up is not possible or is undesirable because of coexisting medical conditions
Age younger than 50 years

primary HPTH in patients with complex comorbid medical conditions, either unwilling or considered unfit for surgery. In addition, glucocorticoids and calcimimetics can be employed during refractory hypercalcemia of metastatic parathyroid carcinoma [25, 27]. In the geriatric population, particularly in elderly postmenopausal women, it has been demonstrated that estrogen replacement therapy combined with either calcitriol or calcium supplements, appeared as effective as parathyroidectomy for the treatment of osteoporosis in the setting of primary HPTH [39–41]. In addition, the combination of calcitriol and calcium may be effective in reducing systolic hypertension associated with HPTH [42, 43]. However, these therapies are not definitive; with adequate preoperative parathyroid localization, experienced parathyroid surgeons may employ minimally invasive techniques with good outcomes in the elderly population [44].

Parathyroidectomy without preoperative localization studies has a high success rate (>95%) and a low complication rate. Complications associated with parathyroidectomy

TABLE 35.4 Pharmacologic treatment for primary hyperparathyroidism

<i>Pamidronate/bisphosphonates</i>	
Dosage	60–90 mg as a single dose
Adverse effects	Leukopenia, fever, and myalgia
Contraindications	Hypersensitivity
Special points	Onset 1–2 days with long half-life
<i>Chronic oral sodium phosphates</i>	
Dosage	1–3 g daily
Adverse effects	Extraskelatal calcifications
Contraindications	Serum calcium >12 mg/dl, serum phosphorus >3 mg/dl
Special points	Not indicated in acute hypercalcemia
<i>Calcitonin</i>	
Dosage	4–8 U/kg every 6–12 h
Adverse effects	Nausea, glucose intolerance
Contraindications	Allergic reactions
Special points	Effective within 2 h; can be used to lower serum calcium while awaiting effect of bisphosphonates
<i>Furosemide</i>	
Dosage	20–40 mg up to three times daily
Adverse effects	Electrolyte imbalance
Contraindications	Anuria, hepatic coma, and hypovolemia
Special points	Hydration is essential
<i>Cinacalcet*</i>	
Dosage	30–90 mg daily
Adverse effects	Nausea, vomiting, diarrhea
Contraindications	Hypersensitivity, and hypocalcemia
Special points	*Off-label use in primary HPTH except parathyroid carcinoma

include recurrent laryngeal nerve injury, transient or persistent hypocalcemia, postoperative hemorrhage, and pneumothorax [45]. Despite this, the specific operative approach has continued to evolve through the influence of a number of synergistic factors, including improvements in preoperative localization studies as mentioned above, rapid intraoperative PTH measurements, and adjunctive surgical technologies such as hand-held gamma detection probes and small video-scopic equipment. The net result has influenced patient selection so that the majority of parathyroid explorations are very well tolerated. However, difficult explorations remain difficult. Therefore, any surgeon performing parathyroidectomy must be facile and comfortable with standard four-gland parathyroid exploration. In fact, experienced parathyroid surgeons today achieve cure rates of up to 98% with both minimally invasive and conventional techniques [46].

The conventional technique for parathyroid exploration requires a bilateral cervical exploration. This operation is usually performed under general anesthesia, although it can be performed under bilateral regional superficial cervical block [47]. The goal is to identify all normal and abnormal parathyroid glands, thus distinguishing single-gland from multigland disease. Patients who have a single parathyroid adenoma undergo curative resection once the gland is removed. In the instance of multigland hyperplasia, a subtotal parathyroidectomy (leaving a remnant of one well-vascularized parathyroid gland in situ) is required. Total cervical parathyroidectomy with immediate heterotopic transplantation of parathyroid tissue is less desirable for patients with sporadic HPTH, but often is employed in the setting of familial HPTH, such as MEN-1.

The conventional approach has been challenged with increasing frequency in recent years, and minimally invasive parathyroid exploration is now performed routinely in several institutions. Three techniques have emerged: image-guided local exploration, most often in conjunction with intraoperative PTH assays; intraoperative gamma probe-guided exploration after sestamibi injection; and, image-guided video parathyroidectomy.

Image-guided local exploration has emerged as the most commonly employed minimally invasive technique. It is dependent on high-quality preoperative imaging, usually in the form of sestamibi scans, ultrasound studies, or, less commonly, CT scans. This technique is appropriate even for patients who have had multiple previous explorations, as long as the preoperative imaging is adequate [48, 49]. When performed by an experienced parathyroid surgeon well-versed in minimally invasive techniques, this surgical procedure can be performed on an outpatient basis and can avoid the risks of bilateral neck exploration and general anesthesia [50, 51]. This technique has become particularly more favorable for elderly patients with primary HPTH and additional comorbidities; these patients often are denied referral for parathyroidectomy because of the associated risks of general anesthesia and bilateral neck exploration.

Studies have shown that minimally invasive parathyroidectomy can be performed safely and can facilitate clinical care in these high-risk patients [52, 53].

Gamma probe exploration involves preoperative administration of ^{99m}Tc -sestamibi to localize the abnormal parathyroid gland. The probe is then used in the operating room to find the area of increased radioactivity. In addition, the gamma probe can be used to measure radioactivity after tumor extraction to confirm the adequacy of resection. Although this technique has not gained widespread acceptance, the curative rates are comparable to the previously described technique [54].

Image-guided video parathyroidectomy has been employed by several investigators. Like the other minimally invasive techniques, preoperative imaging is required to locate the adenoma. The procedure usually requires general anesthesia with or without carbon dioxide insufflation to aid the dissection [55]. There may be very select patients in whom this technique is indicated. However, it is not a common procedure in elderly patients, as it offers no additional benefits for this specific patient population. This technique has not assumed a dominant role in parathyroid surgery in the US.

Clinical Outcomes

In the hands of an experienced parathyroid surgeon, it has been demonstrated that patients who underwent either conventional bilateral neck exploration or minimally invasive parathyroidectomy had equivalent cure rates. The rationale for parathyroidectomy is supported by evidence that in about 80% of patients, the clinical manifestations of primary HPTH improve after successful parathyroidectomy. Thus, fatigue, weakness, polydipsia, polyuria, bone and joint pain, constipation, nausea, and depression improve in most patients. This is also true for associated conditions – new renal stones usually stop forming, osteoporosis stabilizes or improves, pancreatitis becomes less likely, and peptic ulcer disease often resolves. In most patients, fracture risk and weakness also improve, and objective increase in muscular strength has been documented [56–60]. In addition, neurocognitive impairments, confusion, spatial learning deficits, and depression have been shown to improve after successful operative intervention. Patients can resume a regular diet with or without calcium supplementation, and hypercalcemia is not a concern when these patients are hospitalized for other medical conditions [61–65].

However, there is a natural reluctance to subject elderly patients to an operation when the advantages are less clear. Advances in parathyroid imaging resulting in a greater use of targeted or focused parathyroidectomy has opened the way for the inclusion of less fit patients into the potentially operable category. Chen et al. compared demographic and outcome data of elderly patients (>70 years of age) to those of

younger patients (<70 years of age); and found that mental impairment, bone disease, and fatigue were more common in elderly patients, and nephrolithiasis was more frequent in younger patients. Elderly patients presented with more advanced disease, manifested by higher preoperative PTH levels. However, the cure rate, morbidity, and mortality in the elderly were indistinguishable from those of their younger cohorts [66]. Similarly, Bachar et al. found that there was no practical difference in perioperative management and surgical outcomes for patients over the age of 70 years, and concluded that surgeons should consider parathyroidectomy in primary HPTH patients regardless of age [67].

Several quality-of-life studies have been performed using standardized tools such as the SF-36 health survey in patients with primary HPTH, and have demonstrated that patients experience an improvement in health status and quality of life after operative correction [68, 69]. Furthermore, this benefit was independent of preoperative calcium levels [70]. Psychological distress, as measured by the General Health Questionnaire, has also been shown to be ameliorated by parathyroidectomy [71, 72]. The Parathyroid Assessment of Symptoms (PAS), a patient-based outcome tool, was developed specifically for patients with primary HPTH. A multicenter study using this questionnaire indicated that PAS is a reliable measure of the symptoms associated with HPTH, and that these symptoms improve after parathyroidectomy [73].

Both classic and more subtle clinical manifestations of primary HPTH warrant medical evaluation and, in most patients, parathyroidectomy. This especially is true when parathyroidectomy is performed by an experienced parathyroid surgeon, with a success rate greater than 97% and a very low complication rate. Furthermore, with the advent of minimally invasive techniques, these operations can often be done on an outpatient basis. Elderly patients are an especially vulnerable population, and should be referred to experienced parathyroid surgeons who have the knowledge, skill and available technology to perform these surgeries in minimally invasive fashion, with faster intraoperative times, less anesthetic requirements and low operative complications.

For patients with severe bone disease, often evidenced by markedly elevated preoperative blood alkaline phosphatase levels, subsequent “bone hunger” often necessitates postoperative treatment with calcium supplementation and calcitriol [56]. Normocalcemia generally is restored within the first 24 h after a successful parathyroidectomy, and this may be accompanied by mild paresthesia in the extremities. Symptoms may occur while the serum calcium level is within the normal range, reflecting the rapidity of change; however, this is usually transient and does not require treatment. Symptomatic hypocalcemia is more common in the elderly, in those with more severe preoperative HPTH, or in patients with evidence of high-turnover bone disease. Elderly patients may be magnesium deficient, and this may lead to a functional

hypoparathyroidism, which can be corrected by magnesium supplementation. Restoration of normocalcemia can be achieved with calcitriol in combination with supplemental calcium. It is sufficient to maintain the serum calcium within the lower part of the reference range in order to control symptoms. This also provides a greater margin of safety from hypercalcemia, which may be a particular risk in elderly patients with renal impairment [74].

Another and perhaps more important reason for recommending parathyroidectomy is that patients with primary HPTH appear to be at risk for premature death primarily because of cardiovascular disease and cancer, as documented by Palmer et al. and confirmed by Hedback et al. [75, 76] More importantly, the increased death rate, even in patients with mild primary HPTH, can be reversed by successful parathyroidectomy. Patients between the ages of 55 and 70 years seem to receive the greatest survival benefit.

Secondary and Tertiary Hyperparathyroidism

In contrast to the intrinsic feedback inhibition defect of primary HPTH, secondary HPTH is caused by chronic extrinsic overstimulation of otherwise normal parathyroid glands (Fig. 35.4a, b). Although it may result from malabsorption syndromes, celiac disease, or extreme dietary calcium or vitamin D deficiency, secondary HPTH occurs most commonly in the setting of chronic renal insufficiency associated with renal osteodystrophy. The stimulus for PTH hypersecretion is a reduced extracellular calcium concentration and reduced endogenous calcitriol production that is associated with reduced renal function [77, 78].

Tertiary hyperparathyroidism refers to the development, in the setting of longstanding secondary HPTH, of autonomous hypersecretion despite correction of the underlying case of PTH stimulation. This may be suspected when an individual with documented secondary HPTH develops refractory hypercalcemia, or after renal transplantation in a previously dialysis-dependent patient [79].

The distinction between secondary and tertiary HPTH is not critical when considering surgical intervention because refractoriness to medical therapy in secondary HPTH is functionally equivalent to the intrinsically refractory autonomy seen in tertiary HPTH. The indications and rationale for surgical therapy are the same. Elderly patients with renal disease are prone to severe bone loss, and seem to benefit from parathyroidectomy [78].

Clinical and Diagnostic Evaluation

Patients with chronic renal failure (CRF) have considerable morbidity and mortality. Classic clinical manifestations of worsening secondary HPTH are related to osteodystrophy

FIGURE 35.4 (a) Scintigraphic image from ^{99m}Tc -sestamibi depicting four-parathyroid-gland activity (*arrows*) in tertiary hyperparathyroidism. (b) Scintigraphic images from sestamibi single-photon-emission

tomography of the same patient presented in Fig. 35.4a depicting multiple rotational tomographic planes. The right superior and inferior parathyroid glands (*arrows*) are visualized on sagittal view.

(pain, deformities, and fractures), extraskelatal calcifications, and the skin (pruritus and calciphylaxis).

Changes in bone structure due to secondary HPTH are common and begin early in the course of CRF. Renal osteodystrophy includes two major pathologies: osteitis fibrosa cystica and adynamic bone disease. In mixed osteodystrophy, features of both osteitis fibrosa and decreased mineralization coexist. The form and severity of the bone disease depend on the gender and age of the patient; the severity and duration of the CRF; metabolic acidosis; the characteristics of dialysis; calcitriol and PTH levels; dietary calcium and phosphate load; additional medications, particularly steroids; and associated endocrine diseases, such as diabetes mellitus. In addition, parathyroidectomy and renal transplantation can modify acutely the precarious balance of long-deranged mineral metabolism [80].

A disease of high bone turnover, osteitis fibrosa cystica is a consequence of elevated PTH secretion and is characterized by increased osteoclasts, osteoblasts, osteocytes, and fibroblasts. There is a correlation between the serum PTH level and the rate of bone turnover; and the probability of high-turnover bone disease increases with rising serum PTH concentrations. Serum PTH greater than 450 pg/ml is closely related to high-turnover bone disease in hemodialysis and peritoneal dialysis patients. It has become possible to suppress PTH secretion with the administration of calcium and vitamin D; therefore, the frequency of classic osteitis fibrosa

and mixed forms is decreasing, while the frequency of adynamic bone disease is increasing [81].

In contrast to osteitis fibrosa, adynamic bone disease is associated with low levels of serum PTH. This disease is characterized by unequal decreased numbers of both osteoclasts and osteoblasts, with a predominant deficiency of osteoblasts. Low bone formation rates lead to decreased bone mass [17, 81]. In the past, adynamic bone disease also was associated with high aluminum dialysis baths, but this has become less pronounced with modern dialysates.

There are three types of extraskelatal calcifications (systemic calcinosis): visceral, periarticular, and vascular. Visceral calcifications may involve the lungs, breast, myocardium, mitral valve, kidneys, and skeletal muscle. Patients often have hyperphosphatemia, an elevated calcium-phosphorus product, and increased PTH levels. Periarticular calcification or tumoral calcinosis results in calcific periartthritis and small-joint effusions; radiographically, calcifications can be seen around the joint. Vascular calcifications of both large and small vessels occur in 20% of patients with CRF, and may cause falsely elevated blood pressure measurements. Parathyroidectomy rarely affects vascular calcification, but usually diminishes nonvascular calcium deposits [82, 83].

The skin manifestations associated with secondary HPTH include pruritus and calciphylaxis. Pruritus affects up to 85% of hemodialysis patients. Although dramatic improvement of

pruritus has been observed after parathyroidectomy, PTH does not seem to be directly involved in its pathogenesis. Rather, abnormal serum levels of phosphate, calcium, and magnesium may cause pruritus [84].

Calciphylaxis, or calcific uremic arteriopathy, a rare syndrome of disseminated calcification, is a severe complication of secondary HPTH, and results in soft tissue calcification, vascular medial calcinosis, and arteriolar thrombosis leading to ischemic tissue necrosis. Patients present with painful, violaceous, mottled lesions that may progress to skin and subcutaneous tissue necrosis, nonhealing ulcers, and gangrene. Lesions are characteristically located in the hands and fingers, lower extremities, and occasionally lower abdomen. Patients usually have a high calcium-phosphate product, but not necessarily highly elevated PTH levels. The prognosis generally is poor, particularly in patients with truncal and proximal extremity lesions, with mortality approaching greater than 50%. When symptoms and signs of calciphylaxis are identified, the patient should be treated with phosphate binders and timely parathyroidectomy [85, 86]. Necrotic skin ulcers should be treated with standard wound care, debridement, and avoidance of superinfection. For large, non-healing ulcers, hyperbaric oxygen therapy has been employed with mixed results. Sodium thiosulfate has been shown to produce clinical improvement of calciphylaxis lesions. Bisphosphonates have been shown to be effective in animal models of calciphylaxis, and the mechanism of action is believed to be due to inhibition of macrophages and local proinflammatory cytokines as well as binding to calcified vascular smooth muscle cells to inhibit further arterial calcification. Cinacalcet is thought to decrease serum PTH levels and stabilize calcium and phosphate concentrations, and has been associated with improved pain control and ulcer healing. Calciphylaxis remains a poorly understood disease, as most of the data on these therapies consist of case reports [87].

Tertiary HPTH occurs most commonly following renal transplantation in a previously dialysis-dependent patient. Symptoms resemble those of primary HPTH and may include increased bone resorption, nephrolithiasis, and pancreatitis. Increased bone resorption is often exacerbated by preexisting osteodystrophy, and steroid-induced osteopenia. Tertiary HPTH is the main cause of nephrolithiasis in transplanted kidneys, presenting as painless hematuria in the grafted denervated kidney. Pancreatitis, which occurs in 2–6% of kidney transplant recipients, has a prevalence of 11% in those with hypercalcemia [88–90].

Treatment

The initial management of secondary and tertiary HPTH revolves around medical therapy with or without dialysis in order to maintain a stable mineral milieu. This therapy

focuses on dietary phosphate restriction, vitamin D sterols, and calcimimetics [91].

Phosphate retention represents one of the major factors in the development of secondary HPTH. The first step to control serum phosphorus is to reduce phosphate intake. However, the extent of dietary phosphate restriction is limited by malnutrition associated with inadequate protein intake and often, poor patient compliance. Thus, the use of phosphate binders is required in almost all patients, particularly those who are dialysis-dependent. Phosphate binders can be calcium-based, aluminum-based, or neither calcium- or aluminum-based; the choice is dependent on the patient's calcium level [91].

After achieving the desired serum phosphorus levels with dietary restriction and the use of binders, secondary HPTH may often persist due to vitamin D deficiency. In this case, vitamin D should be substituted. Calcitriol is the most active metabolite of vitamin D; however, in the setting of CRF, there are potential adverse effects. Calcitriol promotes the intestinal absorption of calcium and phosphate, leading to hypercalcemia and hyperphosphatemia, with a subsequent rise in calcium-phosphate product, a known risk factor of mortality in CRF. In addition, oversuppression of PTH secretion can lead to adynamic bone disease and may, in turn, further aggravate hypercalcemia and hyperphosphatemia. Therefore, vitamin D should not be administered until the serum phosphorus is under adequate control. Several vitamin D analogs have been developed that retain a suppressive action on PTH and parathyroid gland growth with concomitantly less calcemic and phosphatemic activity. These include paricalcitol, doxercalciferol, and maxacalcitol [92].

The parathyroid CaSR regulates PTH secretion. In secondary HPTH there is underexpression of the CaSR, leading to partial loss of calcium-regulated PTH suppression. Calcimimetics allosterically modulate the CaSR, thereby sensitizing it to extracellular calcium ions. The reestablished calcium sensitivity leads to the suppression of PTH production. In contrast to vitamin D sterols, which show an effect on PTH levels in hours or days by inhibition of PTH synthesis, the modification of the CaSR and the resulting inhibition of PTH secretion leads to changes in serum PTH in minutes to a few hours. The advantage of calcimimetics, like cinacalcet hydrochloride, is the capacity to suppress PTH secretion with concomitant rise in serum calcium and phosphorus [93].

Parathyroidectomy is indicated when medical treatment fails to control progressive secondary HPTH. Clinical manifestations include persistence or worsening of skeletal symptoms, pruritus, and extraskeletal calcifications. Elevated intact PTH levels and a proven high-turnover bone disease are prerequisites for consideration of surgery. Calciphylaxis is an indication for immediate parathyroidectomy (Table 35.5) [86].

Indications for operative intervention in tertiary HPTH are similar to those of primary HPTH, namely, significant hypercalcemia, decline in creatinine clearance, nephrolithiasis,

TABLE 35.5 Indications for parathyroidectomy in secondary hyperparathyroidism

Appropriate medical treatment and elevated PTH levels and high-turnover bone disease with any of the following:
Bone pain that is disabling or dependent on continuous analgesic drugs
Pathologic fractures
Subperiosteal resorption documented on plain radiographic films
Hypercalcemia unresponsive to phosphate restriction and phosphate binding
Hyperphosphatemia unresponsive to phosphate restriction and binding
Severe pruritus
Extraskelatal nonvascular calcifications (systemic calcinosis)
Intractable anemia
Calciphylaxis

TABLE 35.6 Indications for parathyroidectomy after kidney transplantation

Subacute severe hypercalcemia
Persistent hypercalcemia and one of the following:
Deterioration of renal function
Nephrolithiasis
Progressive bone disease
Acute pancreatitis

acute pancreatitis, changes in mental status, or overt bone disease. Mild hypercalcemia alone does not appear to be a serious threat to the patient with a transplanted kidney, and its treatment remains controversial. However, impaired renal function in the presence of elevated PTH and hypercalcemia should be an indication for parathyroidectomy, especially in the elderly patients (Table 35.6) [88].

Preoperative preparation of dialysis patients includes control of hyperkalemia, hypomagnesemia, and hypervolemia with careful evaluation and treatment of hypertension and cardiovascular disease. Patients should receive oral calcitriol before surgery to avoid severe postoperative hypocalcemia. They should be dialyzed no longer than 1 day before parathyroidectomy and then again no later than 2 days after the operation. When parathyroidectomy is performed after kidney transplantation, immunosuppressive medications do not have to be interrupted in the perioperative period. However, replacement glucocorticoid doses should be administered [86–88].

The two accepted operative procedures for the management of secondary and tertiary HPTH are subtotal parathyroidectomy and total parathyroidectomy with immediate parathyroid autotransplantation [94]. The variability of the number of parathyroid glands is well known; in a report on 519 patients undergoing total parathyroidectomy with parathyroid forearm autotransplantation, supernumerary glands were found in 14.5% of patients. The most frequent location of supernumerary glands (39%) was the thymic tongue [95,

96]. Thus, transcervical thymectomy is performed routinely to decrease the risk of recurrent HPTH and to lower the rate of reoperations to the neck [97, 98].

Intraoperative PTH measurement is an established tool in determining the successful removal of parathyroid tissue in patients undergoing surgery for primary HPTH. Recent studies have provided evidence that intraoperative PTH monitoring also may be useful during surgery for secondary and tertiary HPTH. After subtotal or total parathyroidectomy, an appropriate and rapid decline of PTH levels is expected. A persistent elevated PTH, however, can result from non-identified supernumerary glands, and further identification and removal of additional parathyroid glands are indicated [99, 100].

Clinical Outcomes

The overall clinical result is considered good in 70–85% of patients who undergo successful parathyroidectomy. In a few days, bone pain improves in 60–80%, malaise in 75%, and joint pain in 85% of patients. Muscle weakness is alleviated in one third of the patients with improvement of radiologic signs in 95%. Pruritus decreases overnight in almost all patients and disappears in 60–80% [101].

Successful parathyroidectomy improves nonvisceral calcifications in 50–60% of patients. However, it does not change arterial calcification despite reduction in the calcium-phosphate product and PTH. Small peripheral arterial calcification may progress or even develop in approximately 56% of patients after operative intervention [101].

Conclusion

Hypercalcemia is a common finding in the elderly population. It appears to have widely encompassing effects on many aspects of geriatric health, from cognitive and psychiatric decline to diminished function of the cardiovascular, renal, bone, endocrine, and gastrointestinal systems. It may be associated with underlying malignancy, but concomitant intact PTH measurement usually is diagnostic. HPTH peaks in the fifth decade of life, but elderly patients are at increased risk to develop HPTH. Such patients should be evaluated carefully, and surgical interventions, when appropriate, should be undertaken by experienced parathyroid surgeons. With the advent of better imaging studies and minimally invasive operative techniques, elderly patients who may have been considered poor surgical candidates can now undergo safe and successful parathyroidectomy with improved health status, enhanced quality of life, and prolonged life expectancy.

CASE STUDY RESOLUTION

After appropriate medical management of acute hypercalcemia, including intravenous hydration, bisphosphonate and furosemide therapy, the patient's serum calcium decreased to 10.8 mg/dL and her mental status returned to baseline. She underwent a sestamibi scan with SPECT, which revealed increased uptake in the right inferior anterior neck. After adequate medical evaluation, she underwent a

minimally invasive parathyroidectomy with excision of a right inferior parathyroid adenoma. Intraoperative rapid PTH measurement documented adequate resection with a decline from her baseline 200 to 35 pg/ml at 10 min post-resection. The patient returned home the following day with a normal serum calcium level of 9.8 mg/dL, and a post-operative regimen of oral calcium supplementation. At 6 months post-operatively, she remained eucalcemic and did not have any further episodes of nephrolithiasis.

Chapter 36

Adrenal Tumors in Older Persons

Tobias Carling and Robert Udelsman

CASE STUDY

An 88-year-old male with a known left parotid gland tumor underwent a positron emission tomography/computed tomography (PET/CT) scan to rule out malignancy. The PET scan revealed uptake in the left retroperitoneal area, and the CT scan revealed a 4.0×3.0 cm mass of the left adrenal gland. The operation for his parotid gland tumor was postponed, and he underwent biochemical evaluation for endocrine hypersecretion. Twenty-four-hour urine collection revealed elevated levels of epinephrine, norepinephrine, and vanillylmandelic acid (VMA). Plasma levels of free metanephrine and normetanephrines were elevated, whereas serum cortisol, DHEA, potassium, calcitonin, plasma aldosterone concentration (PAC), renin activity (PRA), and 24-h urine collection of cortisol and aldosterone were all within normal limits. His past medical and surgical history are significant for a left parotid gland tumor, long-standing hypertension controlled with a β -blocker and an angiotensin-converting enzyme (ACE) inhibitor, atrial fibrillation, and benign prostatic hypertrophy (BPH). A recent echocardiogram revealed mild aortic stenosis and mitral valve prolapse with an ejection fraction of 55%. He had in the remote past undergone two intraabdominal operations: open cholecystectomy for acute cholecystitis and partial gastrectomy with vagotomy for a duodenal ulcer. His family

history is negative for familial pheochromocytoma. He denies any chest pain, shortness of breath, palpitations, headache, pallor, diaphoresis, or any paroxysms (spells). The patient was started on α -blockade (doxazosin mesylate) and metyrosine and when adequately blocked underwent a laparoscopic left adrenalectomy. The operation was uneventful, although some adhesions were encountered from the prior gastrectomy. The patient remained hemodynamically stable during the operation but developed transient hypotension after ligation of the left adrenal vein. This was promptly controlled with volume expansion and intermittent norepinephrine by the dedicated pheochromocytoma anesthesia team. Postoperatively, the patient remained stable off antihypertensive medications. However, after removal of the Foley catheter, he was unable to void due to urinary retention. He was started on tamsulosin for BPH, discharged home on postoperative day 3, and returned for outpatient removal of his Foley catheter. Histopathological analysis revealed a 4.0×3.2×3.0 cm left adrenal pheochromocytoma. All margins were negative. However, marked cellular atypia and focal capsular invasion was identified, suggesting an aggressive phenotype. A definite diagnosis of malignant pheochromocytoma could not be made in the absence of invasive or metastatic disease. There is no evidence of recurrent disease based on biochemical and radiological surveillance for 3 years.

Introduction

Adrenal tumors are common, especially in older individuals. Numerous autopsy studies have examined the frequency of adrenal tumors, and in a review of 87,065 autopsies, adrenal lesions (>1 cm) were identified in 6% of patients [1]. Similarly, the prevalence of adrenal “incidentalomas” is 4% when detected by abdominal CT or magnetic resonance

imaging (MRI). The incidence of adrenal tumors increases with age. For instance, the likelihood of detecting an unsuspected adrenal lesion on an abdominal CT scan in individuals between 20 and 29 years of age is only 0.2% versus 7% in individuals over 70 years of age [1, 2]. The majority of adrenal tumors are clinically nonfunctioning, benign adrenocortical adenomas and usually do not require surgical intervention. However, surgeons also may encounter elderly patients with functioning benign adrenal tumors (cortisol-, aldosterone-, and catecholamine-producing) as well as malignant adrenal tumors (adrenocortical carcinoma; ACC, malignant pheochromocytoma, and metastasis to the adrenal). The management principles of adrenal tumors in older patients are similar to those in their younger counterparts. However, the diagnosis as well as the management may provide unique challenges in the elderly that are exemplified in the above case presentation: (1) the symptoms of hormone excess may be absent, subtle, atypical, and/or masked by medications, (2) the biochemical diagnosis of endocrine hypersecretion may be cumbersome due to drug interference, (3) the index of suspicion may be too low for an alternative diagnosis to essential hypertension, (4) laparoscopic surgery may be more difficult due to previous open abdominal procedures, (5) unanticipated complications may occur (e.g., urinary retention).

Anatomy and Pathophysiology

Anatomy

The adrenals are paired flat glands with a triangular shape, each weighing about 5 g. The medulla is of ectodermal origin and is derived from the neural crest. It contains homogeneous sheets of cells organized into nests. Cells have large varied nuclei and abundant cytoplasm packed with numerous secretory granules containing catecholamines and other substances specific to chromaffin cells. The cortex is of mesodermal origin and is derived from the adrenogenital ridge. The cortex is organized into three layers, each with a different function. The most superficial layer is the zona glomerulosa, responsible for aldosterone production. The middle zone is the zona fasciculata, containing radial columns of lipid-laden cells that primarily produce cortisol. The inner layer, zona reticularis, stores cholesterol for steroidogenesis and secretes sex hormones. The blood supply to the adrenal is threefold: via the superior adrenal arteries from the inferior phrenic arteries, the middle adrenal from the aorta, and the inferior adrenal artery from the renal arteries. Blood passes from the cortex to the medulla, and the gland is drained by a typically single central vein emptying into the vena cava on the right and the renal vein on the left.

Physiology

Steroid end products secreted by the adrenal cortex are metabolites of cholesterol. The common pathway is conversion of cholesterol to $\delta 5$ -pregnenolone and then progesterone. In the zona glomerulosa, progesterone is converted through several steps to the mineralocorticoid aldosterone. In the other layers of the cortex, progesterone is converted first to 17-hydroxyprogesterone and then to either the 17-hydroxysteroid cortisol or the 17-ketosteroid sex hormones. Each day, the adrenal glands secrete 15–20 mg of cortisol, 25–30 mg of androgens, and 75–125 μ g of aldosterone. The zona fasciculata and zona reticularis are responsible for glucocorticoid production. Secretion of cortisol is controlled via the hypothalamic–pituitary–adrenal (HPA) axis. Hypothalamic corticotropin-releasing hormone (CRH) causes release of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland, which stimulates the adrenal cortex to release cortisol. As cortisol concentration achieves the physiologic range of 15–20 μ g/dl, it exerts a negative feedback on both hypothalamus and anterior pituitary secretion. ACTH has a plasma half-life of 25 min, and cortisol has a plasma half-life of 90 min [3]. ACTH and cortisol production are constant over life in normal, unstressed individuals. Adrenal androgen release is regulated by ACTH, whereas gonadal release of testosterone and estrogen are under a separate pathway of pituitary gonadotrophic control. Androgen production peaks at puberty and progressively declines with advancing age. The mineralocorticoid aldosterone is produced in the outermost layer of the adrenal cortex, the zona glomerulosa. Aldosterone secretion is primarily controlled through a renal pathway. Decreased arterial pressure or decreased serum sodium concentration is sensed by the juxtaglomerular apparatus and the macula densa, respectively. The result is production and release of renin, activating angiotensin I. Within the lung, angiotensin-converting enzyme (ACE) converts most of the angiotensin I to the angiotensin II. Circulating angiotensin II stimulates aldosterone secretion. To a lesser degree, aldosterone secretion is stimulated by direct effects of ACTH and elevated serum potassium. With aging, there is decreased production of aldosterone [4].

Stimulation of the adrenal medulla is via preganglionic sympathetic fibers, causing release of dopamine, norepinephrine, and epinephrine. Sympathetic neural outflow is increased by the fight-or-flight response, fear, emotional stress, upright posture, pain, cold, hypotension, hypoglycemia, and other stress. Norepinephrine exerts negative feedback at the preganglionic sympathetic receptors. With increasing age, there is no change in epinephrine levels, but norepinephrine and total plasma catecholamine are increased. However, this does not seem to be associated with hypertension in the elderly, which is probably due to an increased incidence and

severity of atherosclerosis. This change in the cardiovascular system may also be responsible for the attenuated response to sympathetic stimuli seen in the elderly [4].

Molecular Pathology

Although familial adrenal tumors tend to have an age of onset earlier than their sporadic counterparts, the molecular genetics of such kindreds have contributed to the understanding of adrenal tumorigenesis (Table 36.1). Rare hereditary tumor syndromes predispose to adrenocortical tumor development. These include Li–Fraumeni’s syndrome, Beckwith–Wiedemann syndrome, multiple endocrine neoplasia type 1 (MEN1), and the Carney Complex [5]. Li–Fraumeni’s syndrome is a rare neoplasia syndrome caused by mutations of the tumor suppressor gene *p53* that predispose patients to tumors of several origins (brain, breast, adrenal). Beckwith–Wiedemann syndrome is characterized by increased secretion of insulin-like growth factor 2 (IGF-2), resulting in hemihypertrophy, diabetes mellitus, and adrenocortical tumors in children. IGF-2 overproduction is mostly related to defects in genomic imprinting. Adrenocortical tumors arise in up to 40% of patients with MEN1. Mutations of the tumor suppressor gene *MEN1* on chromosome 11q13 are responsible for the development of MEN1 [6]. Studies of sporadic adrenocortical tumors suggest distinct molecular signatures between adrenal adenomas and ACC [7, 8]. However, detailed understanding of the molecular pathway leading to hormone-producing adrenal adenomas as well as ACC is lacking.

Pheochromocytomas occur either sporadically (80–90% of cases) or in four known familial syndromes – multiple endocrine neoplasia type 2 (MEN2), von Hippel–Lindau

(VHL) disease, neurofibromatosis type 1 (NF 1), and succinate dehydrogenase (SDH) gene mutation [9]. The familial forms of pheochromocytoma are caused by the following genes: *RET* protooncogene, and the *VHL*, *NF1*, and *SDH* (*B*, *C*, and *D*) tumor suppressor genes, respectively. The age at presentation varies widely between the variants as well as between and within individual families. The underlying cause of sporadic pheochromocytoma is largely unknown, although genetic studies have identified several chromosomal loci with alterations in sporadic pheochromocytomas and abdominal paragangliomas. The most common chromosomal alteration is loss of the short arm of chromosome 1 [10].

Evaluation of the Adrenal Incidentaloma

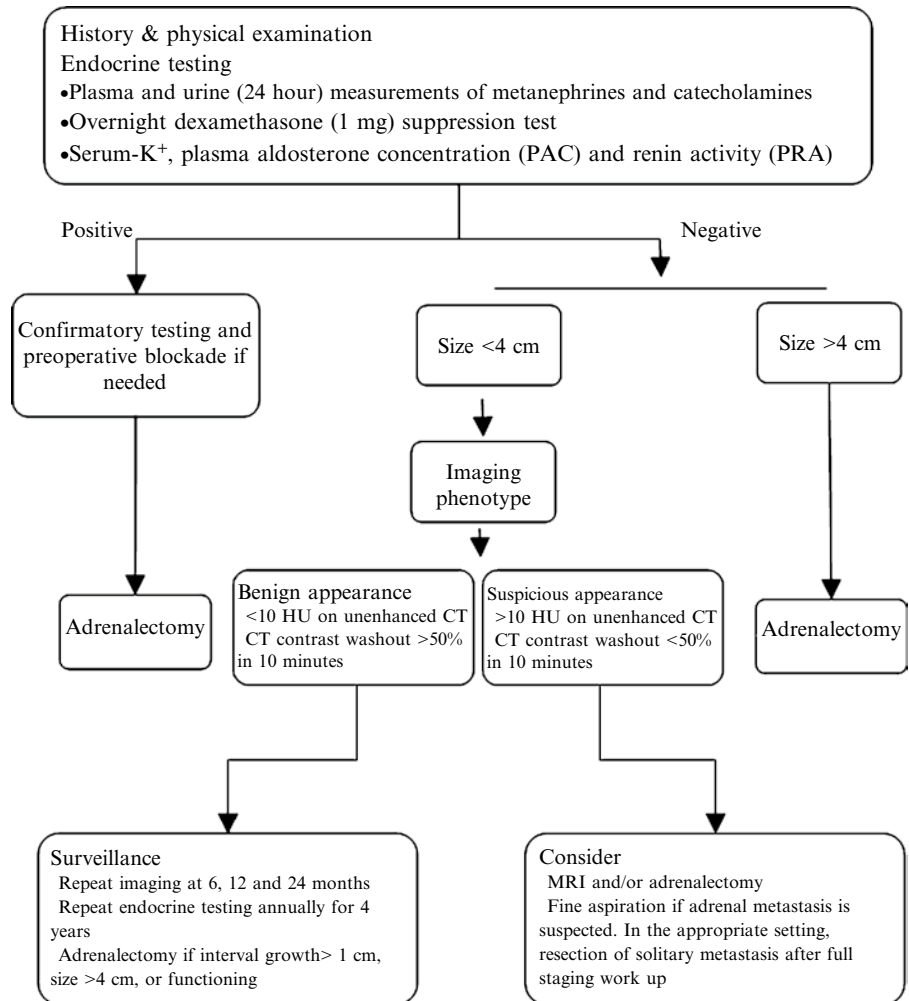

In older persons, given the high and increasing prevalence of adrenal incidentalomas (defined as adrenal lesions >1 cm discovered serendipitously during radiological examination performed for reasons other than adrenal evaluation), a discussion about the management of such patients precedes the section about specific adrenal tumors. The overall goal is to identify patients who have functioning hormone-producing adrenal tumors (cortisol-, aldosterone-, or catecholamine-producing), or malignant adrenal tumors (ACC, malignant pheochromocytoma, or metastasis to the adrenal) [11]. Although all aspects of the evaluation of patients with adrenal incidentaloma have not been prospectively validated, an algorithm based on current clinical experience and data is shown (Fig. 36.1). A detailed history and physical exam is always of utmost importance, focusing on the signs and symptoms suggestive of adrenal hyperfunction or malignant disease (Table 36.2).

TABLE 36.1 Familial adrenal tumor disorders, genetic characteristics, adrenal and common nonadrenal manifestation

Disorder	Responsible gene	Chromosomal location	Adrenal manifestation	Associated manifestations
MEN1	<i>MEN1</i>	11q13	Adrenocortical adenomas	Tumors of the parathyroids, pituitary, endocrine pancreas
Li–Fraumeni	<i>p53</i>	17p13.1	Adrenocortical carcinoma	Sarcomas, breast cancer, brain tumors, leukemia
Beckwith–Wiedemann	<i>Genomic imprinting</i>	11p15.5	Adrenocortical adenomas and carcinomas	Congenital abnormalities, multiple tumors
Carney Complex	<i>PRKARIA</i>	17q23–q24	Nodular, pigmented adrenal tumors	Multiple tumors, pigmented lesions of the skin and mucosae
MEN2A&B	<i>RET</i>	10q21	Pheochromocytoma, often bilateral	Medullary thyroid cancer, HPT in MEN2A. Marfanoid habitus and neuromas in MEN2B
von Hippel–Lindau	<i>VHL</i>	3p25–26	Pheochromocytoma	CNS hemangioblastoma, renal cell carcinoma, and pancreatic tumors
Familial Paraganglioma	<i>SDH B&D</i>	3q13–21, 11q23	Pheochromocytoma, paraganglioma	Leiomyomas and renal cancer
NF 1	<i>NF1</i>	17q11.2	Pheochromocytoma	Cafe-au-lait spots and fibromatous tumors, multiple tumors

MEN Multiple endocrine neoplasia; *NF* neurofibromatosis

FIGURE 36.1 Algorithm for evaluation of an older person with an adrenal incidentaloma. The algorithm should be individualized according to clinical circumstances, the imaging phenotype of the mass, the patient's age, comorbidities, and preferences.

Clinically silent or overt pheochromocytoma occurs in 5% of adrenal incidentalomas. Only about 50% of such patients have hypertension, but clinically silent pheochromocytoma can be lethal [12]. The measurement of fractionated metanephrines and catecholamines in a 24-h urine specimen is recommended for all patients with adrenal incidentalomas (Table 36.2). The detection of elevated levels of fractionated metanephrines, catecholamines, or both has high sensitivity and specificity for pheochromocytoma (91–98%) [2]. The additional measurement of fractionated catecholamines in the 24-h urinary specimen increases the sensitivity of this approach by 5% and is especially helpful in diagnosing patients with dopamine-secreting neoplasms. In older individuals, the measurement of plasma-free metanephrines is less cumbersome than urine collections and has a higher sensitivity for pheochromocytoma (96–100%) [9]. However, the specificity is lower, especially in those older than 60 years of age (77%) [2]. The imaging characteristics of the adrenal mass can also be highly suggestive (but not diagnostic) of pheochromocytoma (Table 36.3 and Fig. 36.2). The findings consistent with pheochromocytoma is increased attenuation on an unenhanced CT scan, prominent vascularity, often

cystic changes, delayed clearance of contrast, and a high signal intensity on T2-weighted MRI.

Clinical or subclinical (i.e., those lacking overt signs and symptoms of glucocorticoid excess) Cushing's syndrome is initially best evaluated with an overnight dexamethasone (1 mg) suppression test [2, 11, 13]. Although the optimal cut-off value is debated, the use of a cortisol level greater than 5 µg/dl is regarded as a reasonable criterion for clinically significant glucocorticoid secretory autonomy [11]. The specificity of the test is 91%, and if the result is abnormal, confirmatory testing should be performed (see section "Cortisol-Producing Adrenocortical Adenomas"). Approximately 5.3% of all patients with an adrenal incidentaloma have autonomous hypersecretion of cortisol (i.e., independent of a normal HPA axis) [2]. However, other studies have identified subclinical Cushing's syndrome in up to 20% of patients with incidentaloma [14–16].

At least 1% of adrenal incidentalomas have proven to be aldosterone-producing adenomas. Screening for hyperaldosteronism is routinely recommended for hypertensive patients who have an adrenal incidentaloma. Given that only a minority (9–37%) of patients with aldosterone-producing adenomas

TABLE 36.2 Symptoms and signs suggestive of adrenal hyperfunction or malignant disease, and suggested initial biochemical screening tests in older persons presenting with an adrenal incidentaloma

Disorder	Symptoms	Signs	Screening test
Pheochromocytoma	May be asymptomatic; Paroxysmal symptoms (spells) often extremely variable; may include palpitation, pallor, tremor, headache, and diaphoresis. Spells may be spontaneous or precipitated by postural change, anxiety, medications (e.g., metoclopramide, anesthetic agents), and maneuvers that increase intraabdominal pressure	Hypertension (paroxysmal or sustained), orthostatic hypotension, pallor, retinopathy, and fever	Plasma and urine (24 h collection) measurements of fractionated metanephrines and catecholamines. Imaging characteristics may be pathognomonic for pheochromocytoma
Cushing's syndrome	May be asymptomatic; symptoms may include weight gain with central obesity, facial rounding and plethora, supraclavicular and dorsocervical fat pads, easy bruising, thin skin, poor wound healing, purple striae, proximal muscle weakness, emotional and neurocognitive changes, opportunistic and fungal infections, acne, and hirsutism	Hypertension, osteopenia, osteoporosis, fasting hyperglycemia, diabetes mellitus, hypokalemia, hyperlipidemia, and leukocytosis	Overnight dexamethasone (1 mg) suppression test; serum cortisol >5 µg/dl is abnormal
Primary aldosteronism	Often asymptomatic. If hypokalemia is present, nocturia, polyuria, muscle cramps, and palpitations	Hypertension, mild or severe; occasionally hypokalemia and hypernatremia	Plasma aldosterone concentration (PAC) and plasma renin activity (PRA) [1]. PAC/PRA ratio ≥ 20 and a plasma aldosterone concentration of ≥ 15 ng/dl are positive results [2]
ACC	May include mass effect (e.g., abdominal pain) and symptoms related to adrenal hypersecretion of cortisol (Cushing's syndrome), androgens (hirsutism, acne, amenorrhea or oligomenorrhea, oily skin, and increased libido), estrogens (gynecomastia), or aldosterone (hypokalemia-related symptoms)	Hypertension, osteopenia, osteoporosis, fasting hyperglycemia, diabetes mellitus, hypokalemia, hyperlipidemia, and leukocytosis	Dependent on symptoms and index of suspicion
Metastatic cancer	History of extraadrenal cancer	Cancer specific signs	Dependent on history

ACC Adrenocortical carcinoma; (1) can be performed while the patient is receiving any antihypertensive drug except spironolactone, eplerenone, or high-dose amiloride; (2) may be laboratory-dependent

demonstrate hypokalemia, the measurement of potassium levels alone is not reliable in screening for hyperaldosteronism [2, 11, 17]. The most reasonable screening test, especially in older individuals, is the ratio of the ambulatory morning plasma aldosterone concentration (PAC) to plasma renin activity (PRA) (Table 36.2). If this ratio is high (≥ 20), it is suggestive of hyperaldosteronism. However, the diagnosis of primary aldosteronism may need to be confirmed by an additional measurement of mineralocorticoid secretory autonomy (see section "Aldosterone-Producing Adrenocortical Adenomas").

A critical aspect of the evaluation of an adrenal incidentaloma is the assessment of malignant potential, which is based on size of the lesion and imaging characteristics. Overall, ACC is found in 4.7% and metastatic disease in 2.5% of

adrenal incidentalomas. For patients who have a nonfunctioning mass, without a prior history of malignancy, the major determinant of whether to recommend surgical excision is the size of the lesion. Lesions smaller than 2 cm have an incidence of malignancy of less than 1%, lesions between 2 and 4 cm have an incidence of 3–5%, lesions between 4 and 6 cm have an incidence of 10–15%, and lesions over 6 cm have an incidence of 30–80%. The National Institutes of Health (NIH) state-of-the-science statement suggested that all lesions larger than 6 cm should have surgical excision and that those less than 4 cm may be observed with serial imaging, as outlined (Fig. 36.1). Some controversy exists whether all patients with lesions between 4 and 6 cm also should undergo adrenalectomy. The imaging characteristics may provide a guide in the management of these patients (Table 36.3). Additionally,

TABLE 36.3 Imaging characteristics of adrenal tumors

Feature	Adrenocortical adenoma	Adrenocortical carcinoma	Pheochromocytoma	Metastasis
Size	Small, usually <3 cm	Large, usually >4 cm, often >10 cm	Medium, usually 3–9 cm	Variable
Shape	Round or oval, smooth margins	Irregular, unclear margins	Round or oval, clear margins	Oval or irregular, unclear margins
Texture	Homogeneous	Heterogeneous, mixed densities	Heterogeneous, cystic areas	Heterogeneous, mixed densities
Laterality	Usually solitary, unilateral	Usually solitary, unilateral	Usually solitary, unilateral	Often bilateral
Unenhanced CT Attenuation	<10 HU	>10 HU (usually >25 HU)	>10 HU (usually >25 HU)	>10 HU (usually >25 HU)
Enhanced CT Vascularity	Not vascular	Usually vascular	Usually vascular	Usually vascular
Enhanced CT Rapidity of contrast washout	Fast	Slow	Slow	Slow
MRI – appearance on T2 weighted image	Isointense to liver	Hyperintense to liver	Markedly hyperintense to liver	Hyperintense to liver
Necrosis, hemorrhage, or calcifications	Rare	Common	Hemorrhage or cystic areas common	Occasional hemorrhage or cystic areas
Growth rate (per year)	Stable or slow (<1 cm)	Rapid (>2 cm)	Usually slow (0.5–1.0 cm)	Variable

HU Hounsfield units

Adrenal hemorrhage, myelolipomas, and cystic neoplasms are usually easily characterized based on their distinctive imaging characteristics [35, 38]. The presence of pure fat within an adrenal lesion on CT is consistent with myelolipoma

FIGURE 36.2 Representative image characteristics of older patients with adrenal tumors. (a) A 68-year-old female with a 4.9-cm right pheochromocytoma (arrow). T2-weighted image on MRI displays a partly cystic lesion markedly hyperintense compared to the liver. (b) A 72-year-old male with a 1.2-cm left adrenal incidentaloma (arrow). The unenhanced CT scan shows a small, round, homogeneous mass with low attenuation. Biochemical evaluation was consistent with primary hyperaldosteronism, and pathology revealed an adrenocortical

adenoma. (c) A 69-year-old female with adrenocortical carcinoma arising from the left adrenal (arrow). The unenhanced CT scan shows a large (15 cm), heterogeneous tumor with irregular, unclear margins. There are multiple areas with mixed densities and necrosis and calcifications. (d) A 65-year-old male with a large (18 cm) cystic lymphangioma of the right adrenal gland. The unenhanced CT scan shows a heterogeneous cystic tumor but with regular smooth margins and a peripheral rim with calcifications.

factors such as age and presence of comorbid conditions may make surgery and anesthesia somewhat riskier. However, the vast majority of these patients can undergo a laparoscopic adrenalectomy, which is typically well tolerated.

Functioning Tumors

Cortisol-Producing Adrenocortical Adenomas

Cushing's syndrome is either ACTH-dependent (Cushing's disease, due to a cortisol-producing pituitary tumor; ectopic Cushing's syndrome, due to an ectopic ACTH-producing tumor) or ACTH-independent and adrenal in origin [18]. The signs and symptoms of Cushing's syndrome are summarized in Table 36.2. The biochemical evaluation is stepwise to first diagnose Cushing's syndrome and then to identify the origin of hypercortisolism (Fig. 36.3).

Patients with adrenal adenomas comprise 15–20% of all cases of Cushing's syndrome, and adrenal adenomas are the most common cause of ACTH-independent hypercortisolism, approximately 50–72% [16]. In one series of 85 elderly

patients, cortisol-secreting adenomas represented 37% of patients undergoing adrenalectomy for Cushing's syndrome and 8% of patients undergoing adrenalectomy for any reason [19]. The female/male ratio for adrenal Cushing's syndrome is as high as 9:1 [16], and the mean diameter of the adenomas is 3.9 cm [20]. However, the prevalence of cortisol-secreting adenomas may be higher than previously thought, and subclinical Cushing's syndrome has been reported in 5–20% of adrenal incidentalomas [14, 15]. It is unclear what percentage of patients with subclinical Cushing's syndrome will develop overt Cushing's syndrome over time. Given the morbidity of long-standing hypercortisolism, an aggressive surgical approach (unilateral adrenalectomy) has been advocated, but long-term health benefits remain to be clarified.

Prior to surgical intervention, careful radiological evaluation with CT and/or MRI is of paramount importance, to differentiate adrenal adenoma from ACC and bilateral adrenal hyperplasia. Bilateral adrenal hyperplasia may be ACTH-dependent, whereas the remaining bilateral lesions are due to ACTH-independent macronodular adrenal hyperplasia (AIMAH) and primary pigmented nodular adrenocortical disease (PPNAD).

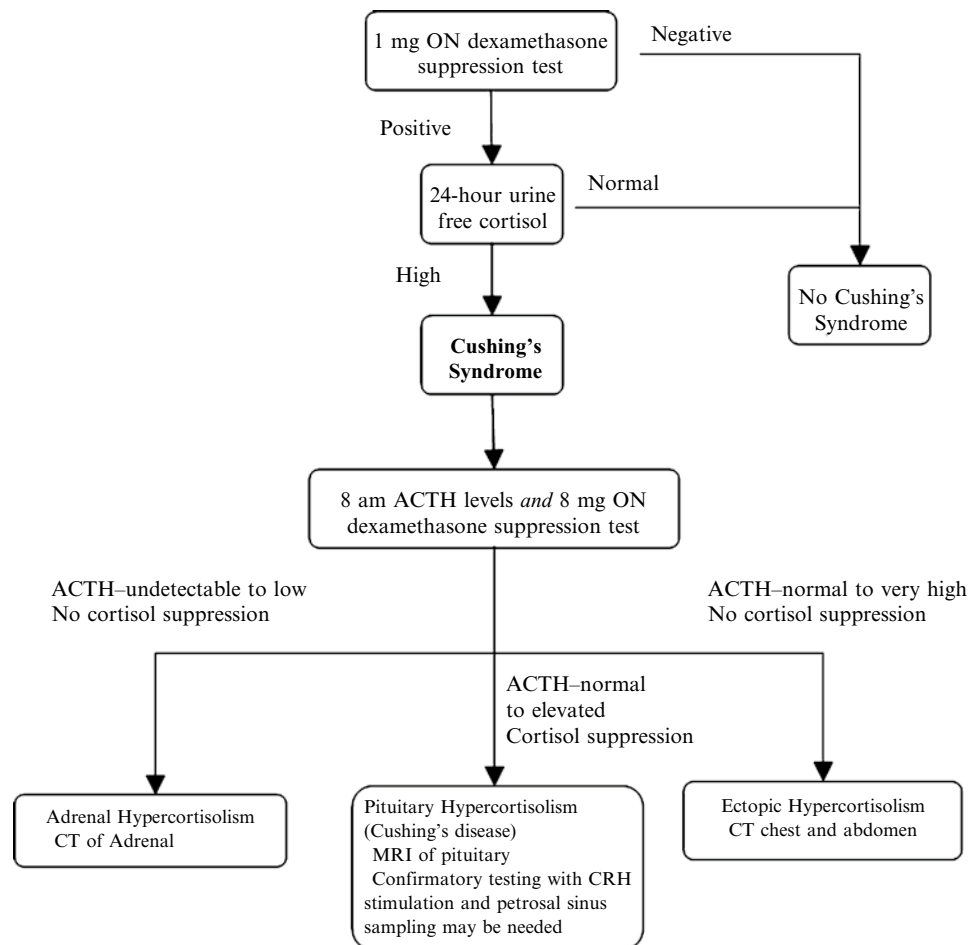

FIGURE 36.3 Algorithm for evaluation of elderly with suspected hypercortisolism. ON overnight; ACTH adrenocorticotrophic hormone; CRH corticotropin-releasing hormone.

The treatment of cortisol-producing adrenocortical adenomas is unilateral adrenalectomy, which can be performed laparoscopically, regardless of age, in the vast majority of cases [21]. Possible contraindications to the laparoscopic approach are a large tumor, suspicion of adrenocortical carcinoma, or the need for concurrent intraabdominal procedures. Tumor characteristics, not age, should determine the approach. Patients with hypercortisolism are at risk for increased morbidity and mortality due to thromboembolism, suppression of immune function, and delayed wound healing.

Elderly patients should not be excluded from surgery based on age alone, but the increased prevalence of associated medical problems during advanced age is associated with increased perioperative morbidity. In the rare cases of bilateral adenomas, AIMAH or PPNAD, bilateral adrenalectomy may be necessary [16]. Cortical-sparing bilateral adrenalectomy, when feasible, is attractive to preserve endogenous cortisol production in such patients [16]. For patients who have undergone unilateral adrenalectomy, replacement doses of glucocorticoids are given and tapered over time until return of function of the HPA axis is documented. The process, both physiologic and morphologic, may take weeks to months or beyond to complete.

Medical therapy for hypercortisolism, which include various steroidogenesis inhibitors, is limited to instances when surgery is not an option, or to briefly optimize a patient prior to definite surgical therapy [22].

Aldosterone-Producing Adrenocortical Adenomas

Conn's syndrome is due to excessive secretion of aldosterone, resulting in the signs and symptoms summarized in Table 36.2. Although it is a rare cause of hypertension (0.5–1.0%), in a series of elderly patients, an aldosterone-producing adrenocortical adenoma was the indication for 20% of adrenal resections (Table 36.4). As stated, all patients with an adrenal incidentaloma and hypertension should be screened for hyperaldosteronism, which is best performed with measurement of plasma aldosterone concentration (PAC) and plasma renin activity (PRA). A ratio of PAC/PRA \geq 20 and a plasma aldosterone concentration of \geq 15 ng/dl are consistent with the diagnosis. This test can be performed while the patient is receiving any antihypertensive drug except spironolactone, eplerenone, or high-dose amiloride. Hypokalemia is only present in 50% of patients with an aldosterone-producing adrenocortical tumor. Occasionally, confirmatory biochemical evaluation is needed with aldosterone suppression testing with either a saline infusion test or 24-h urinary aldosterone excretion test while the patient maintains a high-sodium diet [2]. Aldosterone-secreting

TABLE 36.4 Comparison of indications for adrenalectomy in all versus elderly patients

Diagnosis	% All patients	% >65 years of age
Pheochromocytoma	22–43	19
Adrenocortical carcinoma	18	8
Cushing's syndrome	17–18	22
Nonsecreting adenoma	16–18	31
Hyperaldosteronism	11–19	20
Virilizing/feminizing tumor	6	<1
Myelolipoma	4	<1
Cyst	2–5	<1
Metastasis	1	<1

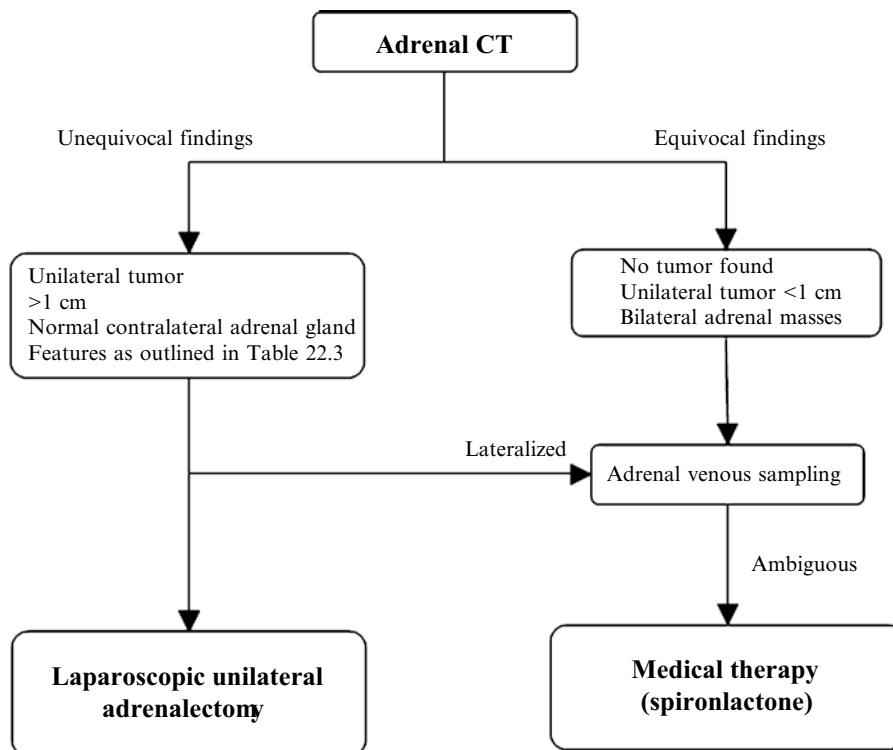

Source: Data from refs. [19, 21, 47, 48]

adrenal adenomas account for 65–70% of primary aldosteronism, whereas the remaining is due to bilateral adrenal hyperplasia (BAH) and other rare causes.

Prior to surgical intervention, careful radiological evaluation with an adrenal CT is of paramount importance. Lateralization of the source of the excessive aldosterone secretion is critical to guide the management of primary aldosteronism. Distinguishing between unilateral and bilateral disease is important because unilateral adrenalectomy in patients with aldosterone-producing adenomas or unilateral adrenal hyperplasia results in normalization of hypokalemia; hypertension is improved in 100% and cured in 30–60% [17]. In BAH, unilateral or bilateral adrenalectomy seldom corrects the hypertension, and medical therapy is the treatment of choice. If the findings are unequivocal on CT, showing a >1 cm unilateral, attenuating lesion with a contralateral normal adrenal gland, no further evaluation is needed. However, if no tumor is found, or the tumor is less than 1 cm, or there are bilateral adrenal masses, further evaluation with adrenal venous sampling (AVS) for measurements of aldosterone and cortisol concentrations is warranted (Fig. 36.4). A ratio of aldosterone/cortisol fourfold greater than the contralateral side is indicative of a unilateral aldosterone-producing tumor, with a sensitivity of 95% and specificity of 100%. AVS is not a simple procedure and requires an experienced radiologist, especially with regard to catheterization of the short right adrenal vein.

Patients at all ages, with an acceptable operative risk and a lateralizing tumor (either by imaging and/or AVS), are candidates for adrenalectomy. Since the vast majority (>98%) of aldosterone-producing adenomas are small and benign, virtually all cases can be performed via a laparoscopic approach. As compared with open adrenalectomy, laparoscopic adrenalectomy is associated with shorter hospital stays and fewer complications. Hypertension is cured (defined as blood pressure <140/90 mmHg without the aid of antihypertensive drugs) in about 50% (range, 35–60%) of patients after unilateral adrenalectomy, with a cure rate as high as 56–77% when the cure threshold was blood pressure less than 160/95 mmHg [17]. Factors associated with resolution of hypertension

FIGURE 36.4 Algorithm for evaluation of an older patient with confirmed primary hyperaldosteronism.

include preoperative use of two or fewer antihypertensive drugs, duration of hypertension less than 5 years, higher PAC to PRA ratio preoperatively, higher urinary aldosterone secretion, or positive preoperative response to spironolactone [17, 23, 24]. Advanced age and longer duration of hypertension have been suggested in some studies to be associated with a lower cure rate [17].

Medical management with spironolactone or amiloride is recommended for patients who do not undergo surgery [17]. Significant improvement can be achieved, but additional antihypertensive medications are needed in about 83% of cases. In the long term, adrenalectomy is more cost-effective than lifelong medical therapy [24].

Sex-Steroid Producing Adrenal Tumors

Androgen-secreting adrenal adenomas are rare. Virilization or feminization in the setting of an adrenal mass is most likely due to an adrenocortical carcinoma, especially in the elderly [25]. Androgens secreted by the adrenal cortex are dehydroepiandrosterone (DHEA) and androstenedione. They exert a direct effect and can also serve as precursors for testosterone and estrogen. Men can exhibit feminization, and women can experience hirsutism or virilization. Biochemical screening is performed when clinical signs are present. Signs of sex steroid excess are investigated in all such patients by measuring urinary 17-OH-progesterone. Urinary testosterone should be

measured in women with virilization, as cases have been reported where testosterone but not 17-OH-progesterone was elevated. Estrogens are measured in men with feminization, as some patients with sex steroid-secreting adrenocortical carcinoma have had normal 17-OH-progesterone but elevated estrogens. When a tumor secreting androgens is detected, treatment is unilateral adrenalectomy, taking care to perform an adequate resection should the tumor prove to be a carcinoma (see section “Adrenocortical Carcinoma”).

Adrenocortical Carcinoma

Adrenocortical carcinomas (ACC) are rare, with a yearly incidence of about 500 new cases in the United States, or about 0.5–2.0 cases per million inhabitants. Age at diagnosis ranges from 0 to 70 years (mean 46 years), and there is a bimodal distribution with peaks during the first and fifth decades. However, older persons do present with ACC and there is an increased incidence in the elderly of hormonally inactive tumors. The prevalence of ACC in cohorts of patients undergoing adrenalectomy is 8% in patients ≥ 64 years, 13% in those with incidentally diagnosed adrenal masses, and 18% in unselected patients. These findings are consistent with the Yale experience between 1997 and 2007, when 8.3% of patients operated on for ACC were above the age of 65 years (unpublished data). ACC is slightly more common in women, and tend to more often be hormonally active.

TABLE 36.5 Staging system for adrenocortical carcinoma (ACC), and percentage at diagnosis

Stage	TNM	(%) At diagnosis
I	T1 (Tumor \leq 5 cm), N0, M0	2.9
II	T2 (Tumor $>$ 5 cm), N0, M0	28.3
III	T3 (Tumor any size, local invasion), N0, M0 or T2, N1 (positive, mobile regional lymph node), M0	23.4
IV	T4 (Tumor any size, gross invasion of adjacent structures) or N2 (positive, fixed lymph node), or M1	45.4

Source: Data from Fraker [25]

The vast majority of patients present with stage III or IV and the overall prognosis is poor with a 5-year survival varying between 20 and 45% (Table 36.5) [25].

Earlier studies reported that about 50% of tumors were functional, but more recent series have noted hormone secretion in up to 79% of cases, most likely due to improvements in assay sensitivity [26]. Often, ACC may secrete multiple hormones and may change secretion according to size, growth rate, and differentiation. The biochemical workup depends on signs and symptoms of hormone excess (Table 36.2) and should also include DHEA-S, 17-OH-progesterone, androstenedione, testosterone, and 17 β -estradiol (only in men and postmenopausal women) [27].

ACC tend to be large with imaging characteristics as outlined in Table 36.3 and exemplified in Fig. 36.2c. Local extension is present in 65% and metastasis in 25% of patients at diagnosis. Common sites of metastasis are lymph nodes, lung, liver, and bone; therefore, preoperative evaluation should include CT of the abdomen and chest. MRI and PET scan can be used to further establish the diagnosis preoperatively, as well as to identify metastatic disease. Fine needle aspiration is not helpful since it will not distinguish between a benign and malignant adrenocortical tumor [11].

The treatment of choice and the only chance for cure for ACC is complete surgical extirpation of the tumor and adrenal gland, en-bloc resection of invaded organs, and if necessary, periaortic/retroperitoneal lymphadenectomy. Noncurative surgical debulking is performed in approximately 20% of the cases, to ameliorate symptoms of endocrine hyperactivity. An open abdominal approach is advocated for ACC, to avoid tumor spillage, capsule rupture and to ensure adequate retroperitoneal resection and lymphadenectomy. Some authors suggest that a laparoscopic adrenalectomy can be considered for tumors that have no evidence of local invasion, extensive lymphadenopathy, or distant metastasis on preoperative imaging, thus ensuring clean resection margins, and are not too large to risk tumor spillage from manipulation. In patients with an aggressive surgical approach, the mean disease-free survival interval ranges from 12 to 22 months, although long-term survivors exist. Even in patients who underwent curative resection, up to 80% of patients developed locoregional recurrence or distant metastases [28].

Nonoperative management includes cytoreductive therapy with transarterial embolizations and radiofrequency ablation (RFA), which may ameliorate symptoms of endocrine hyperactivity [25]. The chemotherapeutic agent most commonly used in ACC is mitotane, which may also be used in the adjuvant setting [29]. The overall response rate has been reported to be between 14 and 36%, but most studies have shown no significant survival benefit [25, 29].

Pheochromocytoma and Abdominal Paraganglioma

Pheochromocytomas are rare catecholamine-producing tumors that derive from adrenomedullary tissue in about 80% of cases and from extraadrenal chromaffin tissue in about 20% of cases [30]. Pheochromocytomas arising in extraadrenal tissue are commonly called paragangliomas or (if in the region of the carotid body or aortic arch) chemodectomas. Regardless of location, pheochromocytomas share similar histopathological characteristics [9]. Pheochromocytomas can cause hypertension via exceptionally high circulating catecholamine levels, accounting for approximately 0.05–0.1% of cases of sustained hypertension. However, about 50% of patients with a pheochromocytoma have episodic or no hypertension [9]. The signs and symptoms associated with pheochromocytoma are summarized in Table 36.2. It has been estimated that in the United States, approximately 40,000 people have pheochromocytoma, with newly diagnosed pheochromocytoma averaging 800–1,600 cases per year in the general population [9]. Although the peak incidence occurs during the age of 30–50 years, older patients develop pheochromocytoma and may be asymptomatic or present with atypical symptoms, which may partly be masked by common medications such as β -blockers.

Measurement of plasma or urinary catecholamines and their metabolites, as well as serum chromogranin A, is the foundation of the biochemical diagnosis of pheochromocytoma. Urinary analysis of catecholamines and metanephrines should be performed in a 24-h urine sample collected in 6 M HCl, whereas plasma is collected in a fasting patient. Urinary metanephrine is the most specific diagnostic assay, whereas measurement of chromogranin A and plasma or urinary metanephrines are the most sensitive [31]. Measurement of urinary vanillylmandelic acid (VMA) has a false-negative rate of 41% in documenting catecholamine excess. In older individuals, the measurement of plasma-free metanephrines is less cumbersome than urine collections and has a higher sensitivity for pheochromocytoma (96–100%) [9]. However, the specificity is lower, especially in those older than 60 years (77%) [2].

The imaging characteristics of pheochromocytomas are summarized in Table 36.3 and exemplified in Fig. 36.2a. CT

and/or MRI is sufficient in the vast majority of patients, but ^{131}I -metaiodobenzylguanidine scintigraphic scanning and PET scan may be useful, especially if there is a suspicion of bilateral, extraadrenal and/or malignant pheochromocytoma. PET imaging using 6- ^{18}F -fluorodopamine, ^{18}F -dihydroxyphenylalanine, ^{11}C -hydroxyephedrine, or ^{11}C -epinephrine are very promising, new, specific radionuclide localization techniques for pheochromocytoma [9]. Familial pheochromocytoma has increasingly been diagnosed due to advances in molecular and clinical genetics and likely represents a higher proportion than the classically quoted 10%. They tend to present at a younger age and more often with bilateral or extraadrenal lesions. Malignant pheochromocytoma occurs in 10–20% of cases and is three times as common in women. Extraadrenal lesions are two to three times likely to be malignant. Malignancy is proven by invasion of adjacent structures, nodal involvement, or metastasis. Sites of metastasis are bone, liver, lymph nodes, lungs, and brain. Histological differentiation between benign and malignant primary tumors remains unreliable.

Once a diagnosis of pheochromocytoma has been made, preoperative (1–2 weeks before surgery depending on response and level of catecholamine excess) α -blockade needs to be started. In older patients with significant cardiovascular comorbidities, this treatment may need to be performed in the inpatient setting [32]. There exist wide-ranging practices, international differences in available or approved therapies, and a scarcity of evidence-based studies comparing different therapies [32]. The overall principle, however, includes α -blockade for 1–2 weeks prior to surgery, with fluid replacement, and the addition of β -blockade if tachycardia is present. Metyrosine (Demser) is an analog of tyrosine that competitively inhibits tyrosine hydroxylase. Calcium channel blockers are also often used successfully either alone or as an adjunct. Phenoxybenzamine (Dibenzylin; irreversible, noncompetitive, α -adrenoceptor blocker) is most commonly used for preoperative blockade and is initially dosed at 10 mg twice a day with increments of 10–20 mg every 2–3 days [32].

The majority of pheochromocytomas and abdominal paragangliomas can be resected via a laparoscopic approach [33]. However, open exploration should be considered in cases of large tumors, known or suspected malignant disease, difficult-to-access periaortic paragangliomas, and when a pheochromocytoma has ruptured preoperatively. The key to safe surgery is effective preoperative blood pressure control, rigid intraoperative pressure management, and clear communication between surgeon and anesthesiologist. Elderly patients and patients with existing ischemic or congestive heart disease may require more meticulously regimented fluid administration, and a pulmonary artery catheter may be used to guide therapy. Recurrent and metastatic pheochromocytoma may be treated with surgical debulking and/or RFA or possibly ^{131}I metaiodobenzylguanidine [34].

Nonfunctioning Tumors

Benign Adrenocortical Adenoma and Myelolipoma

Adrenal myelolipoma and nonfunctioning adrenocortical adenomas are the most common nonfunctioning tumors of the adrenal gland. The incidence increases with age, and as stated, adrenal lesions (>1 cm) are identified in 6% of autopsy studies [1]. The imaging characteristics of adrenocortical adenomas are summarized in Table 36.3, and the presence of pure fat within an adrenal lesion on CT is consistent with myelolipoma [35]. The workup of these lesions follow those of adrenal incidentaloma (see section “Evaluation of the Adrenal Incidentaloma”).

Rare Adrenal Masses

A number of adrenal masses may be incidentally detected, and the differential diagnosis may include adrenolipoma, amyloidosis, ganglioneuroma, granuloma, hamartoma, hematoma, hemangioma, leiomyoma lipoma, neurofibroma, adrenal pseudocyst, lymphoma, and teratoma [36, 37]. Although rare in the United States, various infectious processes may cause an adrenal mass. These include fungal, tuberculosis, echinococcosis, and cryptococcosis [37]. Adrenal cysts can be infectious, lymphangiomatous, or angiomatous endothelial, cystic degenerative adenomas or embryonal retention cysts. Sometimes, the imaging characteristics of these particular lesions are suggestive [38, 39], as exemplified in Fig. 36.2d. Surgical resection may be needed due to mass effect or to prevent rupture, hemorrhage, or infection. Additionally, when malignancy cannot be excluded based on imaging, surgical resection is warranted. Again, the role for adrenal fine needle aspiration is limited to distinguishing adrenal tissue from metastatic tissue and less commonly infection.

Adrenal Metastasis

Metastasis to the adrenal gland occurs, with the most common sources being lung, breast, colon, kidney, and melanoma [40]. The imaging characteristics are variable as summarized in Table 36.2. Adrenal metastases are often bilateral. In select patients with isolated adrenal metastasis, after careful staging, improved survival for patients who underwent resection has been found in various tumor types [41–43]. If the patient elects to undergo resection, metastatic disease to the adrenal gland should be resected in any

way that can give the most oncologic benefit to the patient. A laparoscopic approach may be used as long as oncologic principles are adhered to [42].

Surgical Management and Technique

Laparoscopic adrenalectomy has become the standard of care for the vast majority of adrenal masses. The benefits of minimally invasive techniques for the removal of the adrenal gland include decreased requirements for analgesics, improved patient satisfaction, and shorter hospital stay and recovery time when compared to open surgery [44]. The relative contraindications are size and malignancy, when there is a concern about adhering to oncologic principles. A variant of the minimally invasive approach is posterior retroperitoneoscopic adrenalectomy, which is especially useful in patients with previous open abdominal operations [45, 46]. Open adrenalectomy can be performed via a transperitoneal, retroperitoneal, or thoracoabdominal approach.

Chapter 37

Benign Breast Disease in Elderly Women and Men

Kay O. Lovig and Barbara A. Ward

Physiologic Changes in the Breast

Familiarity with breast microanatomy and physiology aids in understanding benign breast physiology. The female breast is composed of ductal and lobular units. The main breast ducts arise from lactiferous sinuses in the nipple and divide several times to form small ducts and then the smallest ductal elements, or “ductules,” which in fact form the lobular unit of the breast. The ductules also divide and terminate blindly with club-shaped endings. The ductules are sensitive to hormone stimulation; during pregnancy, they proliferate and form the alveolar components of the breast [1].

Ductal and lobular units of female breasts can be seen as early as during the neonatal period. Maternal estrogen, progesterone, mammatrophic peptides including prolactin, and human placental lactogen promote growth and development of fetal breasts. During the neonatal period, the ductal system shows evidence of secretory epithelium and surrounding myoepithelial cells, although these findings involute and a latent phase starts from childhood to puberty [2].

During puberty, hypothalamic synthesis of gonadotropin-releasing hormone (GnRH) begins. This hormone stimulates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary gland. The FSH then stimulates the ovaries, and estradiol synthesis begins. During the first few years of puberty, anovulatory cycles are common. Because of this, estradiol is the primary stimulant of the breast during this period. It promotes the elongation and branching of the ductal system and increases the volume of the breasts with fat deposition. When the luteal phase begins, progesterone stimulates dilatation of the ductal system and differentiates the alveolar cells to secretory cells.

The most dramatic alterations in the anatomy and physiology of the breast occur during pregnancy. Estrogen,

progesterone, prolactin, growth hormone (GH), cortisol, and insulin prepare the breast to lactate. Ductal and lobular units of the breast increase in size and complexity. Endings of the ductules become secretory alveoli during this period. Lactogenesis occurs throughout gestation, but lactopoiesis begins after delivery of the child. Estrogen and progesterone are believed to inhibit secretion of milk during gestation [3].

With aging, both men and women have significant fall in the production of most hormones when compared to young adults. The levels of growth hormone (GH) and insulin-like growth factor-1 (IGF-1) [4, 5], nocturnal melatonin [6], TSH [7], thyroid hormones [8], calcitonin [9], DHEA [10], aldosterone [11], estrogen [12, 13], and testosterone [14] progressively decrease with age in adult men and women. However, the only endocrine system for which there is a well-defined, abrupt, and universal change in function with age is the hypothalamic–pituitary–gonadal axis in women, seen in menopause. Menopause occurs at the mean age of 51 in normal women in the United States [15]. It is associated with a marked decline in the number of developing follicles, and with this, there is a parallel decrease in the concentration of inhibin B, a peptide that inhibits the production of follicular stimulating hormone (FSH), and thus a corresponding rise in FSH. During the earlier stages of menopause, there is preservation of estradiol secretion. However, in the later stage, ovarian secretion of estrogen and progesterone cease, subsequently resulting in breast involution. Lobules are mostly affected in this process. With the progression of involution, glandular epithelium is disrupted and phagocytized. Main ductal systems are least affected; they survive, but their number decreases and some develop cystic changes. Alterations occur in the elastic and collagen fibers, resulting in loss of supporting tissue, and fat deposition increases. The duration of involution of the breast is generally incomplete and variable. Although most of the lobular structures disappear, remnants and mature lobular structures can remain. Patient variability is significant [1, 16, 17].

In the aging male, there tends to be a gradual decrease in testosterone production by the aging testes and an increase in sex-hormone-binding-globulin (SHBG) levels, resulting

K.O. Lovig (✉)
Department of Internal Medicine, Greenwich Hospital,
Greenwich, CT, USA
e-mail: kayolovig@gmail.com

in a fall in the free testosterone concentration with a reciprocal increase in the luteinizing hormone (LH) level. This rise in LH can result in enhanced Leydig cell stimulation and increased aromatization of testosterone to estradiol, thus increasing estradiol relative to testosterone in the aging male.

Gynecomastia

Gynecomastia is a benign proliferation of the glandular tissue of the male breast, which is caused by an increase in the ratio of estrogen to androgen activity. Gynecomastia occurring in middle-aged and elderly men has the highest prevalence at 50–80 years of age, with as many as 24–65% of men being affected [18]. True gynecomastia should be differentiated from both pseudogynecomastia as well as carcinoma, which is far less common. Pseudogynecomastia, which is often seen in obese men, is due to fat deposition without glandular proliferation and does not require further evaluation. Clinical features worrisome for breast carcinoma include a firm, eccentrically located asymmetric mass, often with fixation to the skin or underlying structures. Ulceration, axillary adenopathy, or a bloody nipple discharge may be present [19].

In true gynecomastia, a ridge of glandular tissue will be felt that is reasonably symmetrical to the overlying nipple-areolar complex.

Classification of Gynecomastia

Gynecomastia can be classified based on a number of different parameters, for example, pathogenesis, histopathology, and morphology, with the morphologic classification being based on subjective parameters. Cordova et al. proposed a scheme for morphological classification which can serve as a guide for the appropriate surgical technique once the diagnosis of benign gynecomastia has been confirmed [20]. These patients would have failed medical management as described below. Grade I and II are described as the nipple-areolar complex being above the inframammary fold. With these stages, ultrasound-assisted lipectomy and skin-sparing adenectomy are the procedure of choice. Once the nipple-areolar complex is at the same height as, or at most one centimeter below, the fold, the classification becomes Grade III. Here, it is necessary to remove the redundant skin by means of a periareolar removal of epidermis. Lastly, Grade IV was marked by ptosis, when the nipple-areolar complex is more than one centimeter below the fold. Stage IV requires reduction mammoplasty with upper repositioning of the nipple-areolar complex.

Etiology of Gynecomastia

The etiology of gynecomastia can be due to both physiologic as well as pathologic changes (see Table 37.1). Physiologic gynecomastia is more common in infants and adolescents boys and less so in adult men. However, aging is associated with an increase in the prevalence of hypogonadism. One previous study illustrated 20% of men older than 60 years of age and 50% of men older than 80 years of age were hypogonadal using total testosterone criteria (Table 37.1) [21, 22].

In addition to the increased prevalence of hypogonadism, there are multiple other hormonal changes occurring in the elderly man which likely account for “idiopathic” gynecomastia. First, aging is associated with an increase in body fat, and this adipose tissue is an active site of extraglandular aromatization of testosterone to estradiol and of androstenedione to estrone. In addition, gradual decreases in testosterone production results in a fall in free testosterone with a reciprocal increase in luteinizing hormone (LH). This rise in LH enhances Leydig cell stimulation, leading to increased aromatization of testosterone to estradiol.

Hypogonadism can also be due to pathological causes, which are broken down into primary and secondary hypogonadism. Primary hypogonadism can be due to a congenital abnormality such as Klinefelter’s syndrome or due to testicular trauma, infection, infiltrative disorders, or vascular insufficiency. All of these etiologies of primary hypogonadism cause hormonal changes similar to those seen in the aging man, as described above. It is ultimately the reduction in testosterone production from the testes and a compensatory rise in LH that causes gynecomastia in these patients. Secondary hypogonadism is due to a hypothalamic or pituitary abnormality. Contrary to primary hypogonadism, these patients have a low production of LH, resulting in a low testosterone production rate and a low estradiol production from the testes. The adrenal cortex continues to produce estrogen precursors,

TABLE 37.1 Pathologic causes of gynecomastia

Pathologic etiology	Prevalence seen among men seeking help
Drugs	10–25%
Idiopathic	25%
Cirrhosis or malnutrition	8%
Male hypogonadism primary and secondary	Primary 8%, secondary 2%
Neoplasms	
Testicular-germ cell, Leydig cell	3%
Sertoli cell, sex cord	
Adrenal – adenoma or carcinoma	
Ectopic production of human chorionic gonadotropin	
Hyperthyroidism	1.5%
Renal disease and dialysis	1%

Source: Data from Braunstein [22]

which are aromatized in extraglandular tissue, thus causing gynecomastia.

One of the more prevalent causes of pathological gynecomastia is cirrhosis, which is a consequence of chronic liver disease characterized by replacement of liver tissue by fibrous scar tissue as well as regenerative nodules. Associated with these changes are an increased production rate of androstenedione to estrone and increased conversion of estrone to estradiol, all leading to gynecomastia [23].

Some of the less common causes of pathological gynecomastia are testicular tumors, hyperthyroidism, and chronic renal failure. Testicular tumors are associated with secretion of human chorionic gonadotropin (hCG). These high levels of hCG lead to Leydig cell dysfunction. In addition, hCG stimulates aromatase activity, which converts androgen precursors to estrone and estradiol, ultimately causing a relative increase in estradiol to testosterone production. Hyperthyroidism is often associated with elevated LH levels, again causing increased estradiol relative to testosterone production by Leydig cells.

Chronic renal failure is the progressive loss of renal function over a period of months to years. It is not entirely clear how dialysis and renal failure cause gynecomastia; however, there appears to be Leydig cell dysfunction in addition to decreased metabolic clearance of LH.

Clinical Evaluation of Gynecomastia

When evaluating adult males for gynecomastia, it is important to take a thorough history including all possible medications that can cause gynecomastia, and perform a physical evaluation including a testicular exam. As discussed above, it is imperative to distinguish between gynecomastia and carcinoma, which typically appears as a firm asymmetric mass, possibly with ulceration, axillary adenopathy, or a bloody nipple discharge. If there is a suspicious lesion, mammography can accurately distinguish between malignant and benign male breast tissues and should be performed prior to a biopsy [24]. Gynecomastia is apparent as a triangular or a round area of increased density with flame-shaped margins (see Fig. 37.1). Male breast cancer presents as a well-defined mass eccentric to the nipple, with associated spiculation and calcification. Pseudogynecomastia is demonstrated as an extremely clear mammogram with no significant glandular tissue seen (see Fig. 37.2). There are no set guidelines with regard to mammography for patients who clinically appear to have true gynecomastia alone. Because some studies have found that mammography was able to identify cancer within what appeared to be purely gynecomastia, it is reasonable to include the exam [24]. Similarly, a breast ultrasound may be added when malignancy is suspected as this may also aid in

FIGURE 37.1 Mammogram showing typical gynecomastia.

FIGURE 37.2 Clear mammogram documenting pseudogynecomastia.

targeting a core biopsy to confirm the diagnosis. The workup that is recommended for gynecomastia that is of recent onset or painful, without a clear etiology, is the following laboratory studies: hCG, LH, testosterone, and estradiol. Prolactin levels and thyroid function tests may be required as the algorithm suggests (see Fig. 37.3).

One last but significant cause of gynecomastia is medications and recreational drugs. Although a causal relation is well established with some drugs, the mechanism is unclear for most drugs (see Table 37.2) [25].

Treatment of Gynecomastia

While physiologic gynecomastia is more common among infants and adolescents, it is also possible in adults and the elderly. For this reason, it is recommended that men with gynecomastia initially be observed with a follow-up evaluation within 3 months. During these visits, it is important to identify possible medications or underlying treatable disorders as discussed above. For men in whom no cause can be identified, and the gynecomastia is tender and/or persists more than 3 months, it is recommended that the patient be started

TABLE 37.2 Medications and recreational drugs associated with gynecomastia

<i>Antiandrogens/inhibitors of androgen</i>	<i>Drugs of abuse</i>
Cyproterone acetate	Alcohol
Flutamide, bicalutamide, nilutamide	Amphetamines
Finasteride, dutasteride	Heroin
Spiroinolactone	Marijuana
Ketoconazole	Methadone
OTC herbal, i.e., Tea tree oil derivatives	<i>Hormones</i>
HAART therapy	Androgens
<i>Antibiotics</i>	Anabolic steroids
Ethionamide	Chorionic gonadotropin
Isoniazide	Estrogens
Ketoconazole	Growth hormone
Metronidazole	<i>Psychoactive drugs</i>
<i>Antiulcer drugs</i>	Diazepam
Cimetidine	Haloperidol
Ranitidine	Phenothiazines
Omeprazole	Tricyclic antidepressants
<i>Cancer chemotherapeutic drugs</i>	<i>Other</i>

on a trial of medical therapy. It is important to note that medical therapy for gynecomastia is only effective in the early, active phase of gynecomastia, which is also when it is most

symptomatic (0–12 months). The later phase of gynecomastia (greater than 12 months) is defined by fibrotic changes and disappearance of the inflammatory reaction. It is unlikely that any medical therapy will result in significant regression in the late fibrotic stage.

There are three types of medications that have been used for the early, inflammatory phase of gynecomastia. The first class is androgens (testosterone), which is only beneficial in hypogonadal men [26]. The second class of medications is selective estrogen receptor modulators (SERMS), such as tamoxifen and raloxifene. SERMS appear to decrease breast volume and significantly reduce breast tenderness. Complete breast regression is typically not achieved [27]. Lastly, aromatase inhibitors, which block estrogen biosynthesis, have been trialed to prevent gynecomastia. To date, clinical trials

have not demonstrated an impressive benefit. Gynecomastia is common in men with prostate cancer undergoing androgen deprivation therapy. Medical therapy has limited benefit once gynecomastia is established in this patient population, and therefore, prevention of breast development is the goal. The two main strategies include pharmacologic therapy (antiestrogens or aromatase inhibitors) or radiotherapy [28].

If gynecomastia does not regress spontaneously or with medical therapy, is causing considerable discomfort or psychological distress, or is long-standing (greater than 12 months), then surgical therapy should be considered [29]. The extent of surgery depends on the severity of gynecomastia, but many patients are treated with a combination of direct surgical excision of glandular tissue and liposuction through a periareolar incision.

CASE STUDY

A 65-year-old retired fireman presents with a unilateral tender mass in the left retroareolar position. He is known through the diagnosis and treatment of his wife's early breast cancer, and she has done well. For the past several weeks, he has noted this mass and he is concerned, in part, given his wife's diagnosis. His past medical history is remarkable for hypertension and mild obesity. He has no issues with potency. His medications include atenolol and furosemide. Otherwise, he is healthy, and he reports moderate alcohol intake. He does not smoke.

On exam, the patient is a healthy-appearing male. His breasts are mildly asymmetric with the left being larger than the right. There are no other skin or nipple changes. There is a tender mass deep to the left nipple, located immediately behind the nipple. There is also a small amount of palpable breast tissue deep to the right nipple which is nontender. He has no palpable supraclavicular

or axillary adenopathy. He refuses a testicular exam, but admits that everything is OK in that department.

Mammography demonstrates bilateral flame-shaped tissue in the retroareolar position which is concentric to the nipple. There is no suspicion of cancer.

The patient is offered a trial of observation and consideration for taking tamoxifen. He is not interested in tamoxifen as his wife had fairly significant hot flashes and some weight gain while taking it. After 3 months, he is still experiencing moderate tenderness, and he requests surgical excision. This is accomplished through a periareolar incision as an outpatient. Pathology demonstrates benign breast tissue. He does well but does require a postoperative aspiration of a small seroma in the office. At 3-month follow-up, he is happy with the cosmesis and remains pain-free. He returns a year later with the identical complaint on the right breast and again elects to undergo surgical excision with similar results.

Perimenopausal Benign Breast Disease

Although uncommon, we are faced more frequently with benign breast problems in an aging population. Benign breast disorders are exacerbated by menopause, however, and afterward their frequency sharply declines.

Mastalgia and Nodular Breasts

Mastalgia is a term applied to various conditions where pain is present in one or both breasts. Women commonly present with breast pain, and the etiology is typically puzzling.

Although the clinician realizes that breast pain is rarely serious, patients are quite troubled by it and are usually worried that there may be an underlying malignancy. A thorough understanding of the classifications of breast pain, common etiologies, and treatment strategies is both helpful for the practitioner and reassuring to the patient.

Breast pain can be classified according to cyclic mastalgia, noncyclic mastalgia, and extramammary (nonbreast) pain [30]. Cyclic mastalgia refers to premenstrual breast pain experienced by most women and is accompanied by an increase in breast nodularity. This is accentuated when associated fibrocystic changes, including cysts, can cause focal severe pain, potentially relieved by cyst aspiration. This type of cyclic mastalgia usually resolves after menopause.

Noncyclic mastalgia generally starts in the fourth decade. In 50% of persons affected, it resolves after menopause, but in the other half, it persists [31]. Noncyclic mastalgia in the postmenopausal age group is less likely to respond to treatment but resolves spontaneously in up to 50% of cases [32]. Most patients assume that their pain is related to an underlying breast cancer. It is necessary to perform a thorough physical exam to rule out an underlying mass and to update the patient's mammogram and focal breast ultrasound as indicated. Tumyan et al. reported on 86 consecutive patients with focal breast pain in the absence of a breast mass. In their study, the negative predictive value of mammogram and ultrasound was 100% with a mean follow-up of 26.5 months [33]. This author has cared for two patients, however, who noted focal breast pain with normal imaging and developed very early cases of DCIS and invasive lobular carcinoma. Both had had contralateral breast cancers and had exhibited focal breast pain prior to that diagnosis as well. This should be considered extremely unusual, but as always, it is important to listen to the patient and respect their persistent concern. Additionally, it is reassuring for patients to understand that breast "tenderness" is normal. The breast is a highly sensitive organ, particularly involving the upper-outer quadrants and the nipple, and this sensitivity commonly persists in the elderly.

Prior to initiating therapy for mastalgia, sources of extramammary pain must be ruled out. Angina relating to coronary artery disease is the most critical possibility that must be considered in the elderly. More common, however, and poorly understood by most patients is costochondritis or "Tietze's Syndrome." This pain originates in the joint connecting the sternum to the upper seven ribs, although the second to fifth costochondral junctions are most commonly affected [34]. Chronic pain is described as a dull ache or pressure, but acute attacks are sharp and stabbing. Physical exam demonstrates a reproducible pain when pressure is applied to the area. It is worsened when moving the rib cage or taking a deep breath. Costochondritis can also be related to systemic arthritis, in which the treatment is dependent on the etiology. Otherwise, the mainstays of treatment are the nonsteroidal anti-inflammatories and avoidance of activities that provoke strain to this area. Steroids can also be injected into the specific costochondral junction, in severe, refractory cases. Khan et al. reported on the successful use of 1-ml 2% lignocaine and 1-ml 40-mg depomedrone injections in 104 women with an 83% success rate and no complications [35].

Other sources of extramammary pain include radiating pain from arthritic conditions or neural entrapment of the cervical and thoracic spine. Shingles should also be kept in mind as unilateral breast and back pain may precede the classical presentation with fever and skin blisters.

Mondor's disease is a less well-recognized condition of the breast which presents with a tender cord-like nodularity. This is a thrombophlebitis of the thoracoepigastric vein and most commonly is located superior and lateral to the nipple [36].

It can also be seen postoperatively when a superficial vein has been transected during the procedure. Trauma and radiation therapy can also contribute to this condition. There may be visible evidence of a vertically oriented nodularity as well as a palpable cord with tenderness. The tenderness may last 1–6 weeks although the cord may take longer to resolve. It can be treated with warm compresses and anti-inflammatories.

Hypothyroidism has been associated with breast pain. Although the exact mechanism is not understood, the breast has an affinity for thyroid hormone and iodine. The terminal part of the duct, the acini, and the ducts are lined with iodine-containing cells. When these levels are low, the breast becomes more sensitive to estrogen stimulation [37]. Given the frequency of thyroid disease in mature women, it is reasonable to include thyroid function testing and assessment of related symptoms of hypothyroidism in women with persistent mastalgia.

Once other sources of extramammary pain have been excluded, the patient and clinician can decide about the treatment, if any, for noncyclical breast pain. Caffeine and alcohol can contribute to mastalgia, so this should be mentioned. There are many medications that can contribute to breast pain and should also be assessed. Hormone replacement therapy (HRT) is known to increase breast pain, tenderness, and density. Macrocysts may persist on HRT postmenopausally and contribute to focal and global pain. Some patients are willing to tolerate these breast symptoms in light of the other benefits that HRT affords. Utilizing the lowest dose may reduce breast tenderness. Other medications such as antidepressants, cardiac drugs, and antihypertensives can cause breast pain, tenderness, and galactorrhea. Because these side effects may be uncommon, reviewing the side-effect profile of all newly introduced medications is prudent in an elderly patient with the recent onset of mastalgia.

Medical therapy for mastalgia has not been very simple or scientific in the past. Vitamin E, evening primrose Oil, and vitamin B6 have all been promoted, and for some patients, these remedies appear beneficial, particularly for cyclical mastalgia. Clinical trials, however, have not shown consistent results.

Rosolowich et al. reviewed the issue of mastalgia for The Society of Obstetricians and Gynecologists of Canada. They wanted to provide practice guidelines for Winnipeg Regional Health Authority Breast Health Centre. The results of their extensive review are as follows:

1. Education and reassurance is an integral part of mastalgia and should be the first-line treatment.
2. The use of a well-fitting bra that provides good support should be considered for the relief of cyclical and noncyclical mastalgia.
3. A change in dose, formulation, or scheduling should be considered for patients on HRT. HRT may be discontinued if appropriate.
4. Women with breast pain should not be advised to reduce caffeine intake.

5. Vitamin E should not be considered for the treatment of mastalgia.
6. There is presently insufficient evidence to recommend the use of evening primrose oil (EPO) in the treatment of breast pain.
7. Flaxseed should be considered as a first-line treatment for cyclical mastalgia.
8. Topical nonsteroidal anti-inflammatory (NSAID) gel, such as diclofenac 2% in pluronic lecithin organogel, should be considered for pain control for localized treatment of mastalgia.
9. Tamoxifen 10 mg daily or danazol 200 mg daily should be considered when first-line treatments are ineffective.
10. Mastectomy or partial mastectomy should not be considered an effective treatment for mastalgia [38].

Another study by Srivastava and colleagues examined randomized controlled trials comparing bromocryptine, danazol, EPO, and tamoxifen with placebo. While bromocryptine and danazol produced positive results, tamoxifen was associated with the fewest side effects and was considered the drug of first choice [39]. Other studies have confirmed the benefit of topical NSAIDs as a safe, effective, and rapid treatment modality [40, 41]. The use of toremifene has been controversial given its potential side effects, and lisuride maleate and iodine therapy are also mentioned in the literature.

Ductal Ectasia

Ductal ectasia, or dilatation of the ductal system, is frequently found in postmenopausal women. This can be found on clinical presentation with nipple discharge and nipple retraction or encountered when operating on the breast for other reasons. Grossly, the specimen consists of firm breast tissue with prominent ducts containing pasty or granular secretions. These secretions may be white, yellow, green, or brown. The walls of the ducts are firm as a result of periductal fibrosis, and sometimes calcium is noted in the ducts [42].

There may be spontaneous nipple discharge and nipple retraction, and the condition can be bilateral. The nipple retraction can appear slit-like in ductal ectasia, as opposed to the classic purse-string appearance with an underlying malignancy. This condition is also different from periductal mastitis, which is more common in young patients, associated with smoking, and results in granulomatous fistulization to the skin.

On imaging, ductal ectasia is typically symmetric with ultrasound demonstrating dilated ducts in a symmetrical fashion. Asymmetric and solitary ducts may be pathologic. Intraductal papilloma and carcinoma must be ruled out in these cases. If the patient has no palpable findings and a normal mammogram and ultrasound, it is highly unlikely that

breast cancer is causing the nipple retraction. MRI can be done if further evaluation is warranted. Central excision of the retroareolar ducts can be performed to eliminate a persistent discharge and alleviate fear of malignancy.

Cystic Disease of the Breast

Breast cysts are common in women aged 40–50, particularly common around menopause. They can appear suddenly as a tender, palpable mass or discovered incidentally during radiologic screening.

There are two types of cysts, dependent on the cyst lining. One is lined with apocrine epithelium and the other with flattened epithelium. Simple cysts lined with flattened epithelium arise from dilatation of terminal portions of ductules and are generally small. Sometimes, they coalesce and form larger cysts, and they are regarded as physiologic changes of involution during menopause. Cysts that are palpable are generally apocrine cysts, and they may grow up to 4–5 cm in size. Apocrine cysts also originate from lobular units and also thought to be a physiologic change of the breast because they are common during the involutonal phase of lactation and menopause. Cyst formation is further promoted by taking HRT following menopause [43].

Cysts surrounded by fatty tissue appear as round or oval, well-circumscribed masses on the mammogram. If they are surrounded by breast parenchyma, some of the contour may be obscured by dense breast tissue; generally, the posterior parts of the cysts are indistinct. Because some malignancies of the breast appear as smoothly contoured and round masses, it is recommended to undertake further diagnostic workup, especially in elderly patients. Ultrasound usually detects whether the lesion is cystic or solid. Simple cysts generally have smooth margins, and the contents of the cyst are anechoic. If echos are detected in the cyst, it can be the result of inflammation, intracystic papilloma, and extremely hypoechoic fibroadenoma, or a malignancy. Medullary carcinoma, in particular, must be considered first in the differential diagnosis. Aspiration biopsy aids in the diagnosis. If the fluid is green to brown and the lesion completely disappears after aspiration, it is consistent with a simple cyst and no further workup is necessary. Cyst fluid of this nature need not be sent for cytology. If a patient is postmenopausal and not on HRT, it is reasonable to analyze the fluid. A residual mass after cyst aspiration, rapid refilling of the cyst, solid papillary components in a cyst confirmed by ultrasonography, and atypical cells or papillary cells in a cyst aspirate are all reasons to perform an open biopsy to rule out malignancy [44]. Figure 37.4 depicts a complex cyst with atypical cells seen on aspiration. Excisional biopsy showed associated ductal carcinoma in situ (Fig. 37.4).

FIGURE 37.4 Complex cyst (ultrasound).

Fibroadenoma

Although fibroadenomas are commonly addressed in young patients, they rarely present issues in the elderly. They constitute approximately 12% of all breast masses in postmenopausal women. There are two classic structural types: intracanalicular or pericanalicular. Generally, the clinical examination, radiologic studies, and core biopsy confirm the diagnosis [45–47]. Fibroadenomas involute after menopause and calcify. They are frequently seen on the mammogram associated with central heavy amorphous or peripheral coarse calcifications, sometimes referred to as “popcorn calcifications” (Fig. 37.5).

Fibroadenomas are considered an aberration of normal development. They do not arise from a single cell but from a single lobule and resemble hyperplastic lobules in the breast. They grow and lactate during pregnancy and degenerate during menopause, exhibiting their hormone dependence [47, 48]. In the elderly, fibroadenomas generally become less cellular and hyalinized, and sometimes, they become fibrotic or disappear in the breast without the influence of estrogen. Once the diagnosis is established, excision and observation are the two main options. Patients generally prefer excision, although the risk of their masses becoming malignant is no different from that of normal tissue. The problem, in general, is being certain of the diagnosis of a fibroadenoma, especially in the elderly where the suspicion of breast cancer is justifiably high [47]. Calcified, involuting fibroadenomas in the elderly do not deserve excision if they have been serially followed mammographically. Spiculation, architectural distortion, and fine and

FIGURE 37.5 Mammogram demonstrating benign calcifications associated with fibroadenomas.

irregular calcifications are signs of coincidental cancer in a fibroadenoma, so further workup and treatment are needed in these patients [49].

Benign Breast Calcifications in the Elderly

Mammograms can demonstrate benign calcifications for many reasons, particularly in the elderly. Cysts can calcify, giving an “eggshell” appearance (see Fig. 37.6), and fibroadenomas may calcify as mentioned earlier. Calcifications may also be present secondary to fat necrosis, postsurgical scar, and suture calcification. Arteriosclerotic calcification is common in the elderly and is typically seen as long tubular structures that appear hollow.

Hormone Replacement Therapy and Mammographic Findings

In general, with the start of menopause, the overall density of the breast decreases owing to glandular atrophy and fatty replacement. The current standard for reporting breast density was established by the Breast Imaging Reporting and Data System (BIRADS). Category 1 describes a breast that is “almost entirely fat,” while Category 2 shows “scattered fibroglandular” tissue. Category 3 reflects a “heterogeneously dense” breast, while Category 4 depicts “extremely dense” breast parenchyma.

Continuous HRT may increase mammographic densities in the elderly. Peck and Lowman first reported that HRT

increases benign changes in the breast with involution after discontinuing treatment [50]. The mammographic changes attributed to HRT may be diffuse, symmetric, asymmetric, multifocal, or cystic densities. Roughly, it is accepted that one fourth of patients receiving HRT show evidence of increased breast density. Combination regimens with estrogen and progesterone are believed to produce this effect much more commonly than estrogen replacement alone [51, 52]. Tissue edema, proliferation of periductal connective tissue or ductal and lobular units may be responsible for the density. Patients who have lower baseline density percentages are more likely to develop breast densities with treatment. Generally, it takes months to years for these to develop. Persistence of breast densities in the elderly alters the sensitivity of the mammogram. In a large retrospective review of 8,779 postmenopausal women being screened in western Washington state, HRT was found to lower both the sensitivity and specificity of screening mammograms [53]. Invasive lobular carcinoma is of concern given that it is difficult to detect mammographically to begin with, and HRT may promote its development. Low-dose regimens may be helpful in patients with increased density of the breast, and discontinuation of HRT can be recommended.

Crandall et al. reviewed the association of breast discomfort with increases in breast density. In their study, postmenopausal women were randomly assigned to postmenopausal hormone therapy vs. placebo. New-onset breast discomfort was associated with an increase in mammographic breast density [54]. It has also been demonstrated that additional imaging is frequently required in women with either dense breast tissue or those on HRT [55]. Not surprisingly, it has also been shown that changes in density are dynamic, such that discontinuation of HRT will result in decreases in breast density [56].

Chapter 38

Breast Cancer in Elderly Women

Monica Morrow and Lisa S. Wiechmann

CASE STUDY

An 80-year-old wheelchair-confined diabetic female is s/p right above the knee amputation after failed bypass grafting, and s/p two myocardial infarctions, most recently 3 years ago. She is not felt to be a candidate for revascularization. Her ejection fraction is 20%. She has occasional chest pain at rest. She also has an 80-packs-per-year smoking history, moderately severe arthritis, and mild dementia. She is managed by an endocrinologist, a cardiologist, her family doctor, and a rheumatologist. Her family doctor obtains a screening mammogram that demonstrates a 1.0-cm spiculated mass in the upper outer quadrant of the right breast. Breast exam is normal, and there is no adenopathy.

Management

This patient is highly unlikely to have her life prolonged by the detection of this cancer prior to the development

of a palpable mass. Ideally, she would never have had a screening mammogram. Since she did, optimal management would include obtaining an ultrasound (US) to see if the mass is visible by US. If yes, a US-guided core biopsy would be far more comfortable for the patient than lying prone, with her breast in compression, for a stereotactic biopsy. The core biopsy demonstrates a Grade II, strongly estrogen receptor (ER)-positive and progesterone receptor (PR)-positive, HER-2-negative infiltrating ductal cancer. This patient is an appropriate candidate for primary endocrine therapy with tamoxifen or an aromatase inhibitor. Although removal of the primary tumor optimizes local control, in her case, this would entail needle localization prior to surgery, which would require her cooperation, as would a procedure done under local anesthesia. Her cardiopulmonary status places her at significant risk for general anesthesia. There is no indication for sentinel node biopsy since the identification of nodal metastases would not change her management. She should be followed with clinical breast exam. If a palpable mass develops in the breast, then surgical excision is warranted.

Breast cancer is the most common malignancy in American women aside from skin cancer, and the second leading cause of cancer death, exceeded only by lung cancer. It is estimated that there were 182,460 new breast cancer cases diagnosed in the United States in 2008, and 40,480 deaths. In addition to invasive breast cancer, carcinoma in situ (CIS), the earliest form of breast cancer, accounted for about 67,770 new cases in 2008 [1].

The incidence of breast cancer increases with age, and despite competing causes of mortality, breast cancer remains

a significant cause of death in elderly women. Cancer is the leading cause of death in those 55–74 years of age and is second only to heart disease in the 75+ age group [2]. As life expectancy increases and the elderly population continues to grow, there will be an increasing number of elderly women diagnosed with breast cancer. Despite the high prevalence of this disease in the elderly, they largely have been excluded or discouraged from participating in clinical trials and often are not given the same therapeutic options as their younger counterparts [2, 3].

The goal of this chapter is to review the important issues related to the management of breast cancer in the elderly. These include age-specific issues regarding the value of mammographic screening, the selection of local surgical therapy, the need for adjuvant radiotherapy, the efficacy

Cancer Center, New York, NY, USA
e-mail: morrowm@mskcc.org

and toxicity of systemic therapy, and the effect of mortality due to breast cancer in this population. Because there is no standard definition of “elderly,” for the purposes of this chapter, an elderly patient is defined as one older than 70 years of age.

Epidemiology

Breast cancer incidence and mortality increase with age, with the greatest increase observed during the childbearing years. In Western countries, a continued increase in incidence is seen after menopause, whereas in Asian countries, the incidence decreases in elderly women [4, 5]. Approximately one half of the breast cancers in the United States are diagnosed in women aged 65 years and over. For women in this age group, an incidence rate of 322 cases per 100,000 population was noted in the SEER database [6], compared with 60 cases per 100,000 for women younger than age 65. The incidence rate for women aged 85 years or more rose to 375 cases per 100,000 population.

Although breast cancer incidence rates in the United States increased by 32% from 1980 to 1987 [7], a stabilization in female breast cancer incidence rates during 2001–2003 and a decrease in the number of breast cancer cases diagnosed in 2003 were observed [8]. Data from the National Program of Cancer Registries (NPCR) and the SEER registries [9] indicate that age-adjusted incidence rates for invasive breast cancer decreased significantly in women aged 50 years and older each year between 1999 and 2003, with the greatest decrease (6.1%) occurring from 2002 to 2003 (Fig. 38.1). The largest decreases were seen in women aged 55–59 years (11.3%), 60–64 years (10.6%), and 65–69 years (14.3%). Rates of in situ breast cancer also stabilized from 1999 to 2003 after increasing by more than 6.6% per year since 1981, with women aged 50–79 years experiencing a significant decrease in incidence during this period [10].

Over the past 25 years, the incidence of in situ carcinoma has increased in association with a decrease in regional disease and a stable metastatic disease rate [7]. Between 1987 and 1997, a decrease in breast cancer mortality was observed in the United States, with a 9% reduction in mortality for those aged 70–79 years. Approximately 50% of this mortality reduction is attributed to screening and 50% to improvements in therapy [11]. Despite the reported decreases in breast cancer mortality, it is important to keep in mind that breast cancer represents the underlying cause of death in 54.5, 37.1, and 30.7% of women aged 60–69, 70–79, and 80+ years, respectively, who are diagnosed with the disease [12].

As in young women, infiltrating ductal carcinoma is the most common histologic tumor type in the elderly, accounting for 77–85% of cases [6, 13]. The relatively favorable subtypes

FIGURE 38.1 Age-adjusted breast cancer mortality rates for U.S. Caucasian women per 100,000 population. *Filled squares*, invasive; *diamonds*, localized; *triangles*, regional; *inverted triangles*, in situ; *open squares*, distant (from Chu et al. [7] Adapted with permission of the Oxford University Press).

of colloid and papillary carcinoma are observed more frequently in elderly women but still account for less than 10% of mammary carcinomas even in women aged 85 years or greater [6, 13, 14], whereas inflammatory and medullary carcinoma are seen less commonly in elderly women than in their younger counterparts [6, 14]. Breast cancers in elderly women are more likely to be moderately to well differentiated, contain estrogen receptors, and have a low thymidine labeling index [14].

Screening

Randomized studies have shown that screening for breast cancer with mammography reduces breast cancer mortality by approximately one third, especially for women aged 50–69 years at invitation to screening [15–17]. As life expectancy increases, attention has turned to determining an appropriate upper age limit for population-based mammography screening. Current guidelines are vague, indicating that

chronological age alone should not be the reason for the cessation of regular screening. Theoretically, screening should be beneficial for women aged 70 years or greater, but evidence to support this statement is limited. To date, the only randomized screening trial that included women aged 70 years and greater was the Swedish Two-County trial [17]. In this study, 162,981 women aged 40–74 years were randomized to a screening or a control group. A 31% reduction in mortality from breast cancer and a 25% reduction in the rate of stage II or higher cancers were seen in the group invited to screening, and the benefit extended to patients aged 70–74 years.

Van Dijck et al. [18] reported the results of a nonrandomized trial of screening in 6,773 women aged 68–83 years, enrolled during 1977–1978 and followed through 1990. Women from the same birth cohort in a neighboring city without a screening program served as controls. Over the entire study period, the cumulative mortality rate ratio was 0.80 (95% CI, 0.53–1.22) for the screened women; at 9–13 years after the start of screening, it had decreased to 0.53 (95% CI, 0.27–1.04). A subsequent study by Jonsson et al. [19] attempted to evaluate the contribution of screening to decreasing breast cancer mortality in women aged 70–74 years. Breast cancer mortality for both the study (screened) and control (not screened) groups decreased during the study period, but with a mean screening interval of 22.8 months and a mean follow-up time of 10.1 years, a 24% reduction in breast cancer mortality was estimated in the screened group after adjusting for lead time bias.

In 2000, Smith-Bindman et al. in a study of 690,993 women aged 66–79 years reported that screening mammography was associated with a decreased risk of detecting metastatic breast cancer among elderly women [20]. Taplin et al. [21] retrospectively reviewed data from seven health-care plans dating from 1995 to 1999, comparing women aged 50 years or older who were diagnosed with late-stage (metastatic and/or tumor size ≥ 3 cm; $n = 1,347$) or early-stage (control subjects, $n = 1,347$) breast cancers. The odds of having late-stage breast cancer were higher among women not undergoing screening (OR = 2.17, 95% CI, 1.84–2.56; $p < 0.001$); failure to screen was significantly associated with age > 75 years (OR = 2.77, 95% CI, 2.10–3.65), as well as lower socioeconomic status.

Mandelblatt et al. [22] used a decision analysis model to determine whether mammographic screening extends life for women aged 65 and greater in the presence and absence of comorbid conditions. Patients were stratified into age groups of 65–69, 70–74, 75–79, 80–84, and 85 years or greater. In each age category, women were further stratified into those with average health, those with mild diastolic hypertension, and women with symptomatic congestive heart failure, to determine the effect of comorbid conditions on screening benefit. Screening was found to save lives for

elderly women of all ages, although the magnitude of benefit decreased as the severity of the comorbidity increased. For a woman with breast cancer, screening prolonged life 617 days for the woman of average health aged 65–69 years, and 311 days for women in the same age group with congestive heart failure. The prolongations of survival for women older than 85 years in the same health groups were 178 and 126 days, respectively. The cost-effectiveness of annual screening ranged from \$13,200 to \$34,600 per year of life saved. In comparison, the cost per year of life saved by treating mild to moderate hypertension in the nonelderly is \$16,000–\$72,000 [22]. These estimates of cost are based on the use of annual screening mammograms. Moskowitz [23] calculated that owing to the longer lead times seen with breast cancer in older women, most of the benefits of screening could be obtained with a 2- to 3-year interval between studies.

Boer et al. [24] used a model incorporating the natural history of breast cancer and the known effect of screening to identify the optimum upper age limit for screening. Using a model in which preclinical duration of breast cancer was assumed not to increase after age 65, no upper limit for screening benefit was identified. If the duration of the preclinical phase was “pessimistically” assumed to increase in the elderly, screening up to age 80 was found to be of benefit. In a study of 2,067 million screening exams performed between 1998 and 2000, the overall breast cancer detection rates in the 50–69 and 70–75 age groups were, respectively, 4.2 and 14.2 per 1,000 initially screened women. The referral, biopsy, and detection rates were substantially higher in women aged 70–75 years than in their younger counterparts, and a significant trend toward a smaller tumor size distribution was observed [25]. These findings, summarized in Table 38.1, suggest that mammographic screening is a beneficial technique in the elderly.

The current United States Preventive Services Task Force guidelines recommend screening mammography for women aged 50–75 years [26]; however, a number of studies indicate that breast cancer screening in the elderly, whether by

TABLE 38.1 Outcomes of screening in older women

	Age group (years)

Source: Data from Fracheboud et al. [25]

mammography or clinical breast examination, is underutilized. The National Cancer Institute Breast Cancer Screening Consortium [27] reported the results of 7 population-based surveys of women aged 50–74 years. In five of the seven studies, the rates of breast screening by mammography and breast examination in the 70–74 years age group were lower than those reported for other ages. This occurred despite the fact that more than 90% of women surveyed had a regular source of medical care.

Lack of awareness of breast cancer risk and screening procedures in elderly women contributes to the underutilization of these techniques. Leathar and Roberts [28] identified a lack of knowledge among elderly women about breast cancer, a pessimistic attitude toward disease outcome, and embarrassment about being examined as major barriers to screening. Fox et al. [29] conducted a telephone survey of 724 women aged 65 years and older to assess factors influencing the use of mammography. Only physician recommendation predicted a recent mammogram, with age, race, and health status found to be insignificant factors.

In 2001, data from the state-based Behavioral Risk Factor Surveillance System (BRFSS) and the National Health Interview Survey (NHIS) confirmed that the percentage of women who reported receiving mammography and clinical breast exam within 2 years was lower among older women (56.7% of women aged 70 years and older) compared with younger women (71.1% of women aged 50–69 years). Among both groups, those unable to perform a major activity of daily living were less likely to report receiving mammography within 2 years. Interestingly, most (62.7%) women aged 70 years and older reported having no activity limitation, and only 5.5% reported being unable to perform a major daily activity [30].

In 2007, Field et al. studied women aged 65 years or older when diagnosed with early-stage invasive breast cancer ($n = 1,762$). They assessed mammography use during 4 years of follow-up and found that the percentage of women having mammograms after treatment declined significantly during the studied time frame from 82% in the first year posttreatment to 68.5% in the 4th year of follow-up. Women at higher risk of recurrence (breast conservation without radiation therapy or higher stage) were less likely to have yearly mammograms, as were women without visits to breast cancer surgeons or oncologists, suggesting that underutilization of mammography is a problem for women at all levels of breast cancer risk [31].

Local Therapy of Breast Cancer

What constitutes appropriate local treatment for the elderly woman with breast cancer remains controversial. In the past,

when mastectomy was the standard surgical therapy, the major debate in older women centered on dissection of the axillary nodes. The emergence of breast-conserving surgery and sentinel lymph node biopsy as accepted modalities for the local therapy of breast cancer, and the development of endocrine therapies such as tamoxifen and the aromatase inhibitors have increased the available options for local treatment in this population. When evaluating therapeutic options, it is important to consider not only the immediate morbidity and mortality of treatment but also the efficacy of the therapy in maintaining local control for the duration of the woman's life. Current options for the local management of breast carcinoma in the elderly include mastectomy, breast-conserving therapy consisting of excision and irradiation, or excision alone, and endocrine therapy.

Mastectomy

Mastectomy remains a common treatment in the elderly patient. A modified radical mastectomy includes removal of breast tissue, the underlying pectoralis fascia, and the axillary lymph nodes. In patients with clinically negative axillary lymph nodes, the modified radical mastectomy has been replaced by total (simple) mastectomy plus sentinel lymph node biopsy, an operative technique that is discussed later in this chapter. The 30-day operative mortality rate of any type of mastectomy is uniformly low, and the procedure is physically well tolerated. In a review of the SEER data from 1960 to 1973, Schneiderman and Axtell reported a 30-day operative mortality rate of 0.4% for the 37,745 patients treated during that period. For women aged 75 or older, the operative mortality was 0.8% during 1960–1966, and 0.9% during 1967–1973 [32]. Similar results have been noted in other studies, with mortality rates less than 4% commonly observed [33–36]. Davis et al. reported a 3% mortality rate for women aged 80 or older treated by mastectomy and a 7% incidence of major complications [33]. Hunt et al. in a study of 94 patients reported a complication rate of 20% in elderly patients, but the operative mortality was still only 1% [34]. Wound problems accounted for most of the complications in this series, while Kessler and Seton found cardiovascular and neurologic problems to be the most common cause of postoperative morbidity in their series [35]. Data on the morbidity and mortality of mastectomy in the elderly are summarized in Table 38.2. In patients with severe comorbidities, mastectomy has been performed using local anesthesia and regional nerve blocks [37]. Mastectomy under local anesthesia alone using the tumescent technique of infiltrating dilute lidocaine with epinephrine (25 ml of 1% lidocaine [250 mg] and 1 ml of 1:1,000 epinephrine [1 mg] in 1 L of Ringers lactate) via an infusion pump has also been reported [38]. Although

mastectomy is an excellent method for obtaining local control of breast cancer with a minimum number of outpatient visits, and although elderly women can undergo the procedure safely, these results are obtained at the expense of cosmesis.

Breast-Conserving Surgery in the Elderly

Since 1970, multiple prospective randomized trials have compared survival after breast conservation treatment to survival after mastectomy for stage I and II breast cancer. No survival advantage has been noted for mastectomy. Although most of these trials did not include women older than 70 years, the biologic rationale for breast preservation can be extrapolated to the elderly population. Several studies have suggested that elderly women may have a lower rate of breast recurrence after partial mastectomy and radiotherapy than their younger counterparts [39–41]. Fourquet et al. reported a 97% rate of control at 10 years for women older than 55 years compared to 85% for women aged 33–45 years and 71% for women aged 32 years or younger in a series of 518 patients [40]. Veronesi et al. [41] and Clark et al. [39] have also reported a decreasing frequency of breast recurrence with increasing age. Some of these differences in local failure rates may be due to a higher incidence of adverse pathologic features, such as an extensive intraductal component or lymphatic invasion in young women, but older women appear to have lower local failure rates even after correction for pathologic features.

In addition, local recurrence rates can be affected by a number of treatment factors, such as the extent of surgical resection, the status of the surgical margin, and the use of adjuvant tamoxifen. In the National Surgical Adjuvant Breast Project (NSABP) B-14 trial, 2,644 axillary-node-negative patients, 38% of whom underwent breast-conserving therapy, were randomized to receive tamoxifen or placebo. After a median follow-up of 10 years, the rate of recurrence in the

breast was 14.5% in the placebo arm compared to 3.4% in the tamoxifen group [42]. Thus, in women treated with breast-conserving therapy, including breast irradiation and tamoxifen, the incidence of local failure is low, and the small risk of a second surgery is not an appropriate reason to recommend that elderly women routinely undergo mastectomy. The standard contraindications to breast-conserving therapy (Table 38.3) used to determine the suitability of young women for breast-conserving therapy are applicable in older women as well [43].

High rates of mastectomy in the elderly have been attributed to patient choice. Some studies have indeed shown that BCT is chosen less frequently as age increases [44–46]. In contrast, Bleicher et al. [47] examined the role of age in the surgery decision-making process by surveying 1,279 patients aged 79 or younger from two SEER program registries. A majority of patients (80.3%) underwent BCT. There were no differences in patient preference for mastectomy on the basis of age, and in a logistic regression analysis, age and comorbidities were not significant predictors of mastectomy use.

The necessity for adjuvant radiotherapy in patients treated with breast conservation is a matter of particular interest in the elderly population. The Early Breast Cancer Trialists' Collaborative Group (EBCTCG) overview of randomized trials included ten trials of post-BCT radiotherapy with a total of 23,500 patients. The main analyses of local recurrence, breast cancer mortality, and overall mortality were stratified by age into five groups (<40, 40–49, 50–59, 60–69, and >70 years) [48]. The relative risk of recurrence, comparing those allocated to RT with those not, was about 0.3 in every trial, corresponding to a 5-year risk of local recurrence of 7% in the RT group versus 26% in the control. The absolute effects of post-BCS RT on local recurrence were greater in younger than in older women (5-year risk reductions of 22, 16, 12, and 11% for those aged <50, 50–59, 60–69, and >70 years, respectively). The proportional risk reduction for breast cancer mortality was less pronounced than that for local recurrence, with one breast cancer death averted at 15 years for every four local recurrences prevented in year 5. The lower absolute benefit of RT in older women coupled with the long follow-up period needed for mortality reductions to be observed makes it unlikely that RT will have a major impact upon survival in this population [48].

FIGURE 38.2 Overall survival in patients with ER-positive breast cancers 2 cm or less in size randomized to treatment with tamoxifen alone or tamoxifen plus irradiation. No survival difference between groups was observed (from Hughes et al. [50] Copyright © 2004 Massachusetts Medical Society. All rights reserved).

A similar age-related difference in the magnitude of benefit achieved with a boost dose of radiation was demonstrated in a randomized trial by Bartelink et al. [49] Although the use of a boost resulted in a statistically significant reduction in local recurrence in all age groups, the absolute benefit ranged from 10.4% at 10 years in women aged less than 40 years to approximately 3% in those older than 60 years [49].

Although the value of RT in the setting of BCS in the general population, and to some extent in elderly patients, has been demonstrated, the argument that older age may be associated with lower rates of recurrence, less aggressive tumor biology, and increased comorbidity has prompted investigation into the need for RT after breast-conserving surgery in this subgroup of patients. Hughes et al. [50] designed a prospective randomized trial that included 636 women aged 70 years or older who were randomly assigned to receive tamoxifen plus radiation therapy or tamoxifen alone to examine the benefit of RT in older women with small breast cancers. Eligibility criteria included ER-positive clinical stage I (tumor < 2 cm, clinically node negative) breast carcinoma treated by lumpectomy. At a follow-up of 5 years, the locoregional recurrence rate was 1% in the tamoxifen + RT group versus 4% in the tamoxifen alone group ($p < 0.001$). There were no significant differences in the rates of mastectomy, distant metastases, or overall survival between groups (Fig. 38.2). These findings suggest that lumpectomy plus adjuvant tamoxifen is a reasonable treatment choice for women aged 70 years or older with small, ER-positive breast cancers.

Practical issues, such as the difficulty in traveling to RT appointments daily for 6 weeks, play a significant role in the omission of RT in elderly women, and studies have examined the feasibility of alternative methods of radiation delivery. Kirova et al. [51] examined outcomes in a retrospective study of 367 women aged 70 years or greater treated with

conventional RT (50 Gy, 25 fractions, 5 fractions weekly) or hypofractionated RT, which delivered a total dose of 32.5 Gy in five fractions of 6.5 Gy once weekly. At a median follow-up of 93 months, no differences in breast cancer deaths or local-recurrence-free survival were observed between the 50 patients receiving hypofractionated RT and those treated with conventional RT. The 5- and 7-year local-recurrence-free survival rates were 94% and 91% for the hypofractionated group. The Ontario Clinical Oncology Group reported one of the first trials of hypofractionation [52] in which 1,234 women with node-negative breast cancer and clear margins of excision after breast-conserving surgery and axillary dissection were randomized to accelerated hypofractionated whole-breast irradiation (AHWBI) of 42.5 Gy in 16 fractions over 22 days, or a more standard course of whole-breast irradiation (SWBI) of 50 Gy in 25 fractions over 35 days. The study was first reported in 2002 with a median follow-up of 5.8 years. The incidence of local recurrence at 5 years was 3.2% in the SWBI arm and 2.8% in the AHWBI arm, with no difference in cosmetic outcome. These results have been confirmed with additional follow-up, suggesting that this is an appropriate approach for older women who need to receive RT based on higher risk tumor characteristics [52]. In recent years, hypofractionation has also been used to deliver partial-breast irradiation (PBI). PBI is defined as the delivery of radiation to the surgical cavity plus a 1–2 cm margin after breast-conserving surgery. The rationale for PBI is that most local recurrences occur at the primary tumor site or immediately adjacent to it, rather than elsewhere in the breast. Numerous techniques have been developed, including interstitial brachytherapy, a single-source balloon catheter brachytherapy, three-dimensional conformal treatment with external beam, and intraoperative treatment (IORT). However, long-term outcomes are not yet available for any techniques of PBI. In addition, many of the patients selected for PBI are at very low risk for local recurrence in the absence of RT, raising questions as to whether the favorable outcomes reported in early nonrandomized studies are applicable to a wider spectrum of women with breast cancer. In spite of these concerns, the very brief period of time needed for treatment with PBI (5 days, or on the day of surgery in the case of IORT) make this an attractive approach for study in elderly women.

Overall, breast irradiation has been shown to be well tolerated in the elderly population. A tolerance study by Wyckoff et al. demonstrated that radiation dose, duration of therapy, number of treatment interruptions, and toxicities were no different in women older than 65 years compared to women aged less than 65 years [53]. When considering whether to omit breast irradiation after limited surgery, it is important to remember that most local failures occur within 6 years of surgery, leaving many elderly women at risk of this occurrence. Irradiation is well tolerated in the elderly population, and chronologic age alone is not an indication for its omission from breast-conserving therapy. In patients who do not

undergo breast irradiation, a wider surgical resection (quadrantectomy) appears to decrease the risk of local recurrence.

Sentinel Lymph Node Biopsy

The sentinel node is defined as the first lymph node/s to receive drainage from a particular cancer and can be identified by lymphatic mapping with a blue dye, a radioactive tracer, or both. Injection of the breast tissue around the tumor, the subareolar space, and the skin overlying the tumor have all successfully been utilized to identify a sentinel node. The success rate for identification of the sentinel node in prospective, multi-institutional studies is greater than 95% and improves with experience [54, 55]. When identified, the sentinel node is an accurate predictor of the status of the remaining nodes in the axilla in more than 90% of cases [54, 56, 57]. In the American College of Surgeons Oncology Group (ACOSOG) Z10 trial, increasing patient age was significantly associated with failure to identify a sentinel node [55], with the failure rate increasing from less than 1% in women aged less than 50 years to 2.7% for those aged 70 years and older ($p=0.0004$). Others have reported excellent outcomes for SN biopsy in older patients. Gennari et al. reported a sentinel node identification rate of 100% in 241 consecutive patients aged 70 years or older who underwent sentinel node biopsy [58].

In the past, many elderly patients were not offered axillary staging because the complications associated with axillary lymph node dissection were felt to outweigh the potential benefits of the procedure. The sentinel lymph node biopsy technique allows patients with clinically node-negative breast cancer to undergo axillary staging with a significant decrease in morbidity. There are complications associated with the procedure, however. After 6 months of follow-up in the ACOSOG Z10 trial, decreased range of motion was observed in 4% of patients, axillary paresthesias in 9%, and lymphedema in 7%. Although paresthesias were more common in younger women, the incidence of lymphedema increased with age [59]. Thus, it is important to ensure that knowledge of nodal status is important for overall patient management prior to performing a sentinel node biopsy, since excellent outcomes have been reported after observation of the axilla in older women.

The International Breast Cancer Study Group conducted a prospective, randomized trial of axillary dissection versus observation in women aged 60 years and older [60]. The median patient age was 74 years, and all patients received tamoxifen. At a median follow-up of 6.6 years, axillary recurrence as a first event was observed in 2% of patients and did not differ between groups. This low rate of axillary failure is particularly noteworthy since most of the study participants did not receive radiotherapy. Differences in quality of life

TABLE 38.4 Comparison of the morbidity of SN biopsy and axillary dissection

Symptom	SN biopsy (%)	Axillary dissection (%)
Pain	8–14	23–72

SN Sentinel node

favoring no axillary surgery were present in the first 6–12 months postoperatively but were minimal with longer follow-up. This study indicates that axillary observation is associated with a low risk of axillary recurrence but that when axillary dissection is necessary, it can be performed with a limited effect on quality of life. The impact of knowledge of axillary nodal status on treatment has been examined, with changes in planned therapy occurring in 14–38% of patients based on knowledge of nodal status [61, 62]. In aggregate, these studies suggest that when knowledge of axillary nodal status will not change therapy, axillary observation is a safe approach. When axillary staging is indicated, sentinel node biopsy is the procedure of choice, and axillary dissection can be safely carried out with acceptable morbidity in patients presenting with nodal involvement and those found to have metastases to the sentinel nodes. The morbidity of sentinel node biopsy and axillary dissection is compared in Table 38.4 [63–65].

Axillary dissection is an effective method for maintaining local control in the axilla with isolated axillary failures seen in only 1–2% of patients after the procedure [66, 67]. Major complications of axillary dissection, including injury or thrombosis of the axillary vein and injury to the motor nerves of the axilla, are uncommon, although significant short- and long-term morbidity are associated with the procedure (Table 38.4). Of the potential sequelae of the procedure, lymphedema of the arm is potentially associated with the greatest disability. The incidence of lymphedema following axillary dissection ranges from 1.5 to 62.5% [68–71] depending on the definition used, the length of follow-up, the method of detection employed, and the population studied. Several studies have suggested that older age is a risk factor for the development of lymphedema. Pezner et al. [71] noted lymphedema following breast-conserving treatment (including RT) in 25% of women aged 60 or older compared to 3 of 46 younger women (7%) ($p=0.02$). Other studies have failed to identify an association between age and lymphedema [68–70]. Axillary dissection has also been shown to cause pain and decreased upper arm mobility [72], factors that can cause significant functional impairment in women with pre-existing limitations due to neurologic disease or arthritis. In patients with microscopic nodal involvement, axillary irradiation is an alternative to dissection to maintain local control [73], but in the presence of clinically evident,

histologically confirmed nodal disease, axillary dissection remains the procedure of choice because failure rates after irradiation alone are higher than those seen with surgery in this clinical setting.

Primary Endocrine Therapy as an Alternative Local Therapy

Because of concerns regarding the morbidity and mortality of conventional surgical therapy for breast cancer in elderly women with comorbid conditions, considerable attention has been given to the use of tamoxifen as a primary treatment. In 2007, Hind et al. reviewed the evidence from randomized trials comparing primary endocrine therapy to surgery, with or without adjuvant endocrine therapy and/or radiation, in women aged 70 years or older [74]. Seven studies were included in the review, three reporting outcome data on surgery versus primary tamoxifen and four analyzing surgery plus endocrine therapy versus primary tamoxifen. Only one study selected patients on the basis of ER status. When comparing surgery alone to primary endocrine therapy, no significant difference in overall survival between interventions (HR 0.98, 95% CI, 0.74–1.30, $p=0.9$) was noted. One trial [75] reported adequate summary data to show a significant difference in progression-free survival (PFS) favoring surgery (HR 0.55, 95% CI, 0.39–0.77, $p=0.0006$). In the three trials comparing surgery plus adjuvant endocrine therapy to primary endocrine therapy [76–78], there was a nonsignificant trend in favor of surgery plus endocrine therapy (HR 0.86, 95% CI, 0.73–1.00, $p=0.06$). Only one trial [77] reported adequate data on PFS to calculate a significant difference favoring surgery plus endocrine therapy (HR 0.65, 95% CI, 0.53–0.81, $p=0.0001$), and two trials [76, 77] showed a significant decrease in local recurrence favoring surgery plus endocrine therapy (HR 0.28, 95% CI, 0.23–0.35, $p<0.00001$). These results are summarized in Table 38.5. The results of this review are based on a limited number of small studies of variable methodological quality, with significant heterogeneity among studies. Nonetheless, this review demonstrates that primary endocrine therapy is inferior to surgery plus endocrine therapy for the local control of breast cancer in ER-unselected, medically fit older women, independent of the type of surgery (mastectomy or wide excision alone). The meta-analysis showed no significant difference in overall survival between the two treatments, although one trial showed a small but significant survival advantage for surgery with adjuvant endocrine therapy where follow-up was extended to 13 years [76]. This review suggests that primary endocrine therapy should only be offered to women with ER-positive tumors who are not surgical candidates or who refuse surgery. In a cohort of women

with reduced life expectancy due to significant comorbid disease, primary endocrine therapy may be an appropriate treatment choice. The ESTEEM trial (Endocrine +/- Surgical Therapy for Elderly Women with Mammary Cancer), a national trial in the United Kingdom, will evaluate selection criteria for the use of primary endocrine therapy and hopefully clarify the indications for its use [74].

Systemic Therapy

Adjuvant therapy has come to play an increasingly large role in breast cancer management; however, its role in elderly women remains controversial. The value of adjuvant systemic therapy (endocrine therapy and chemotherapy) in the general population is best estimated from the meta-analysis of the Early Breast Cancer Trialists' Collaborative group which now includes 15 years of follow-up on more than 100,000 women entered on breast cancer clinical trials [79].

Tamoxifen is well established as an effective endocrine therapy for postmenopausal, ER-positive women with node-positive or node-negative breast cancer. The 2005 update of the meta-analysis by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) [79] demonstrated that only for ER-positive disease, adjuvant tamoxifen reduced the annual breast cancer death rate by 31% in all age groups (50, 50–69, and, >70 years) and that the absolute risk reduction after 5 years of tamoxifen was found to be similar for younger and older women [79].

Adjuvant therapy with tamoxifen for 5 years has been the standard of care for women with early-stage, endocrine-responsive breast cancer for many years [79]. However, the partial estrogen agonistic activity of tamoxifen and other selective ER modulators (SERMs) increases the risk of endometrial cancer and thromboembolic events [80]. Aromatase

inhibitors (AIs) are an alternate form of endocrine therapy that profoundly reduce the already low-circulating endogenous levels of estrogens in postmenopausal women by blocking the synthesis of estrogens in nonovarian tissues, including breast tissue [81]. AIs have been shown to be similar or superior to tamoxifen as first-line treatment for locally advanced and metastatic breast cancer [82], as well as in the adjuvant setting [82–84]. However, the side effect profiles of the AIs and tamoxifen differ, with AIs being associated with an increased risk of osteoporosis bone fractures and musculoskeletal complaints, and tamoxifen with an increased incidence of venous thrombosis, endometrial cancer, and cataracts. Crivellari et al. [85] have recently investigated whether the observed effects of letrozole compared to tamoxifen identified in the Breast International Group (BIG) 1-98 trial differed by age to determine whether treatment recommendations should be modified for elderly patients. In the elderly, letrozole significantly improved disease-free survival and was effective in reducing relapses, including distant metastases, when compared to tamoxifen; even though no convincing differences were observed in thromboembolic or cardiac events in the elderly group, data in the older (aged 64–75 years) cohort indicated that thromboembolic events appeared more common with tamoxifen and cardiac events with letrozole. Letrozole was also associated with a higher incidence of bone fractures, independent of age [85]. The choice between an AI and tamoxifen in the individual patient is often made on the basis of preexisting conditions, such as the presence of significant osteoporosis or a history of deep venous thrombosis, which would influence the risk/benefit ratio of one of the drugs.

There is considerable controversy regarding the use of adjuvant chemotherapy in elderly women. The EBCTCG overview [79] only included about 1,200 older women in trials of chemotherapy versus no chemotherapy, making it difficult to draw firm conclusions about efficacy, although the proportional reductions in recurrence and death were smaller in older women than in their younger counterparts. Chemotherapy is an appropriate treatment for many elderly patients with early breast cancer, but its use requires careful consideration of life expectancy, comorbidity, functional status, and other factors. Unlike endocrine therapy, toxicity can be substantial with a major effect on functional status. For healthy elderly women with hormone-receptor-negative tumors and life expectancies of at least 5 years, chemotherapy should be considered for node-positive patients and high-risk node-negative patients; the added value of chemotherapy to endocrine therapy can be estimated using the Adjuvant! program (www.adjuvantonline.com). A sample calculation from Adjuvant! is presented in Table 38.6.

Data indicate that women 65 years and older with node-positive breast cancer treated with newer state-of-the-art

CMF cyclophosphamide, methotrexate, 5-fluorouracil; AC doxorubicin, cyclophosphamide; T tamoxifen; 3rd Gen third generation chemotherapy (i.e., AC plus a taxane)

chemotherapy regimens derive the same proportional benefits in relapse-free and overall survival as younger patients [86]; these benefits are more prominent in ER-negative, node-positive patients [87]. In comparing the efficacy in elderly patients (older than 65 years) of standard (CMF or AC) chemotherapeutic regimens versus capecitabine, an oral agent thought to be well suited for use in the elderly; Muss et al. have recently demonstrated that capecitabine was inferior to standard therapy [88].

Systemic therapy includes endocrine therapy, chemotherapy, and more recently, HER2-directed therapy. Trastuzumab combined with chemotherapy significantly improves survival in HER-2-positive patients compared to treatment with chemotherapy alone [89, 90]. Cardiac toxicity, reversible in most cases, is a major side effect of trastuzumab, and its incidence increases with age and anthracycline use. Elderly patients with HER-2-positive tumors at high risk for recurrence should be considered for nonanthracycline trastuzumab containing regimens such as docetaxel, carboplatin, and trastuzumab (TCH) if cardiac toxicity is a concern [91].

The decision to use adjuvant systemic therapy in elderly women must take into consideration coexisting morbidities and functional status; these may affect a woman's ability to tolerate breast cancer treatment and may decrease survival, regardless of age. The effects of comorbidity on survival can be reliably estimated from mathematical models that are publicly available [92]. This is important in view of the fact that nonbreast cancer causes of death are substantial in women aged 70 years and older, even in those with axillary nodal metastases [93] (Fig. 38.3).

FIGURE 38.3 Causes of death (breast cancer vs. nonbreast cancer) by stage at diagnosis in women aged 70 years and older at diagnosis (from Schairer et al. [93] Adapted with permission of the Oxford University Press).

Additional clinical trials are needed to answer questions concerning the risks and benefits of adjuvant therapy in elders.

Patterns of Care in the Elderly

A number of studies suggest that age at breast cancer diagnosis is a major determinant of the type of therapy received. Outcome data concerning nonconventional breast cancer treatment in the elderly is conflicting, but studies have shown that a large portion of elderly patients do not receive conventional treatment for breast cancer. In 2001, Gadjos et al. retrospectively analyzed risk factors, presentation, pathologic findings, treatment, and outcomes of 206 women older than 70 years compared with those of 920 younger patients undergoing potentially curative operations for breast cancer between 1978 and 1998 [94]. Patients older than 70 years had fewer mastectomies, were less likely to undergo axillary node dissection, postoperative radiation, and chemotherapy, and received tamoxifen more frequently with no difference in rates of local and distant recurrence. In this series, undertreated elderly patients (54% of patients older than 70 years) were significantly older, but despite undertreatment by conventional criteria, the rates of local recurrence and distant metastasis were not increased in comparison with conventionally treated elderly patients. Enger et al. [95] also found that in their study of 1,859 women older than 65 years, women aged 75 years and older or with higher comorbidity indices were more likely to receive nonstandard primary

tumor therapy, to not receive axillary lymph node dissection, and to not receive radiation therapy after breast-conserving surgery.

More recently, Owusu et al. [96] have investigated whether the observed age-related disparities in breast cancer survival were related to differences in treatment received, by evaluating 659 women aged 65 years or older and treated for early breast cancer. In accordance with Enger et al., they found that women older than 75 years were less likely to receive axillary lymph node dissection, radiotherapy, definitive primary therapy, chemotherapy, and guideline therapy. This translated to a 7% absolute decrease in breast cancer-specific survival for women older than 75 years compared to those aged less than 75 years. Findings from this study indicated that as many as 66% of women aged greater than 75 years, and 45% of women aged 65–75 years received less than guideline therapy. These data are consistent with previous studies that demonstrate receipt of suboptimal therapy among elderly patients with early-stage breast cancer [97]. Owusu et al. showed that receipt of guideline therapy in the cohort of older women with early-stage breast cancer evaluated in their study was associated with improved outcomes, particularly among the very old.

Healthy vs. Frail Elderly Patients

Almost 30% of all invasive breast carcinomas occur in women older than 70 years [98]. By the year 2030, an even larger portion of breast cancer patients will be aged 65 years or older,

and many will be affected by comorbid conditions. It is important to distinguish healthy from frail elderly patients and to develop clinical tools that guide clinicians when planning care. The following principles have been proposed for the management of *frail* elderly women. The benefit of screening mammography in these patients is questionable, and a clinical breast exam is likely to identify breast cancers that warrant intervention. Endocrine therapy may be a reasonable primary therapy in older, frail women with hormone-receptor-positive lesions. For ER-negative and PR-negative lesions, excision of the primary tumor may be adequate. Adjuvant endocrine therapy may be appropriate in frail elders with high-risk hormone-receptor-positive breast cancer; chemotherapy is rarely indicated regardless of tumor status. The majority of frail elders with metastases will have hormone-receptor-positive breast cancers, and endocrine therapy should be considered; those with receptor-negative tumors may be treated with single-agent chemotherapy or supportive care measures. Oncologists need to acquire the skills to appropriately identify frail elders so that they select appropriate therapies that will minimize toxicity and maintain quality of life.

Finally, when considering *healthy* elderly breast cancer patients, the data included above suggest that compliance with consensus recommendations for definitive locoregional treatment, usually defined as breast surgery with evaluation of the axillary lymph nodes and radiation therapy in patients undergoing breast-conserving procedures, is warranted. Standard guidelines for adjuvant systemic therapy, including chemotherapy, should also be utilized in this group [99].

Summary

- Screening mammography in healthy women up to age 75–80 years appears beneficial. It is not indicated in frail elders.
- Healthy elderly breast cancer patients should undergo surgery of the primary tumor (excision to negative margins or mastectomy) using standard selection criteria.
- Good local control is obtained with excision alone for T1-, ER-positive tumors. Radiotherapy should be given for others undergoing breast conserving therapy.
- Sentinel node biopsy is the axillary staging procedure of choice for clinically node-negative women if the finding of nodal metastases would alter treatment.
- Axillary dissection remains standard management for patients with macrometastases in the axilla.
- In frail elders, primary endocrine therapy (tamoxifen or an aromatase inhibitor) is the appropriate management of hormone-receptor-positive breast cancer.
- In the rare frail elderly patient with a hormone-receptor-negative tumor, excision alone may be the appropriate therapy.

Chapter 39

Diabetes in the Elderly

Klara Rosenquist and Kitt F. Petersen

Diabetes Mellitus

Diabetes mellitus is a metabolic disease characterized by hyperglycemia, resulting from a relative or absolute deficiency of insulin [1]. Type 2 diabetes is the most common chronic metabolic disease in the elderly, affecting ~30 million individuals 65 years of age or older in developed countries [2]. It is estimated that approximately 40% of people over the age of 65 have diabetes or impaired glucose tolerance (IGT) [3, 4] (Fig. 39.1).

The exact pathogenesis of the development of diabetes in the elderly remains unknown; however, epidemiological studies have shown that the transition from the normal state to overt type 2 diabetes in the elderly is typically characterized by deterioration in glucose tolerance [5, 6], which is due to relative or absolute insulinopenia. One current hypothesis holds that muscle insulin resistance develops with aging and leads to increased demand for insulin secretion by the beta cells in order to compensate for the insulin resistance. This continuous high demand for insulin secretion may over time cause beta-cell failure and thereby lead to overt type 2 diabetes. Several studies in the elderly have documented insulin resistance, independent on body weight, and found that insulin concentrations are two- to threefold increase in response to a standard oral glucose tolerance test (OGTT) [7]. The reason for muscle insulin resistance as a consequence of aging is still unclear. However, there is now strong cross-sectional evidence that insulin resistance in muscle can be attributed to accumulation of lipids (specific fatty acid metabolites such as diacylglycerol), which specifically blocks insulin signaling and thereby cause tissue-specific insulin resistance [8–12]. Application of magnetic resonance spectroscopy (MRS) studies to directly measure intramyocellular lipid content (IMCL) in muscle of healthy, normal

weight, sedentary older people has shown that the IMCL content is ~twofold higher in the older individuals when compared with young matched for body mass index and activity [7], suggesting a similar relation between increased IMCL and muscle insulin resistance in older as in young individuals [12]. This lipid accumulation in the muscle cells is likely caused by imbalance between delivery of fatty acids to the muscle cell and the rate of oxidation within the cell. In support of this, MRS studies of mitochondrial ATP synthesis and basal rates of substrate oxidation via the tricarboxylic acid (TCA) cycle in vivo in young and elderly subjects have shown that both sides of mitochondrial function are reduced by ~40% in the elderly when compared with the young, suggesting that oxidation of lipids within the muscle is reduced in normal aging and thereby may be contributing to the build-up of lipids inside the muscle cell [7] (Fig. 39.2). Other factors may be involved in causing insulin resistance such as a systemic low-grade inflammation and the release of proinflammatory factors (adipocytokines) from adipose tissue such as adiponectin, IL-6, TNF-alpha, RBP-4, and other inflammatory factors, which are elevated in obesity and in type 2 diabetes [13]. These factors are not likely to be part of the early development of muscle-specific insulin resistance and no abnormalities in any of the adipocytokines have been found in healthy, normal weight, older individuals [7]. It seems likely that increases in adipose tissue mass in obesity and type 2 diabetes may contribute to chronic inflammation and proinflammatory states by increasing the recruitment of macrophages, which in turn, act in a feed forward mechanism to induce the release of proinflammatory cytokines that may contribute to systemic insulin resistance [14].

In this context, no signs of systemic inflammation or elevation of circulating adipocytokines have been consistently found in lean, young, healthy, insulin resistant offspring of parents with type 2 diabetes, a group that has muscle-specific insulin resistance [9, 15, 16], strongly suggesting that inflammation is not a primary factor in the early development of insulin resistance in muscle [15].

The link between muscle insulin resistance and the progression to overt type 2 diabetes is dependent on relative

TABLE 39.1 2003 American Diabetes Association diagnostic criteria for diabetes mellitus

Diabetes mellitus

A random serum glucose level ≥ 200 mg/dL plus classic diabetes symptoms

Fasting glucose level ≥ 126 mg/dL

Glucose level ≥ 200 mg/dL at 2 h during a standard OGTT

Impaired glucose tolerance (IGT)

Glucose level ≥ 140 mg/dL and < 200 mg/dL at 2 h during a standard OGTT

Impaired fasting glucose (IFG)

Fasting glucose ≥ 110 and < 126 mg/dL

or actual defects in pancreatic beta-cell function such that insulin secretion is insufficient for the appropriate lowering of postprandial blood glucose. Since pancreatic insulin secretion is a highly energy requiring process, it is currently speculated that reductions in beta-cell mitochondrial function could explain the development of defects in insulin secretion in the elderly and thus explain the high prevalence of diabetes in the elderly [7, 17].

The diagnosis of type 2 diabetes mellitus in young and elderly is similar as outlined by The Diabetes Expert Committee of the American Diabetes Association in 2003 (Table 39.1). The diagnosis is based on meeting one of three criteria: a random plasma glucose of ≥ 200 mg/dL confirmed on a subsequent day by a fasting plasma glucose (FPG) level

of ≥ 126 mg/dL, a 2 h plasma glucose of > 200 mg/dL using the standardized OGTT (75 g of anhydrous glucose dissolved in water), or a random plasma glucose of ≥ 200 mg/dL with associated symptoms of polyuria, polydipsia, and unexplained weight loss [1]. The guidelines also distinguish a classification of altered glucose metabolism called impaired fasting glucose (IFG) and IGT to define a category of individuals that are at increased risk of developing diabetes over time. The diagnosis of IFG is made when an individual has FPG concentrations > 110 mg/dL but < 126 mg/dL, and IGT when 2-h plasma glucose values of the OGTT are ≥ 140 mg/dL but < 200 mg/dL [1].

The ADA recommendations for glucose control are an FPG of 70–130 mg/dL and a hemoglobin_{A1c} (Hb_{A1c}) level of $< 7.0\%$ in adults [18]. According to past epidemiological studies, lowering Hb_{A1c} into a normal range (i.e., $< 6\%$) is supposed to be associated with a decreased risk of diabetic complications. However, recently this has been questioned from data suggesting a potential increase in mortality with intense glucose lowering strategies in patients with type 2 diabetes and lowering of Hb_{A1c} to $< 6\%$ [19]. This study was terminated early given an increase in all causes of mortality of participants (mean age 62) in the intensive therapy group [19]. It is therefore prudent for the clinician to set individualized goals for elderly patients based on history of severe hypoglycemia, cognitive function, life expectancy, and comorbid conditions [18].

Therapeutic management options in elderly individuals are similar to those of younger individuals. As in younger individuals, dietary interventions and lifestyle modifications, including weight loss (medical nutrition therapy or MNT), are the cornerstone of diabetic management [18]. Dietary recommendations suggest weight loss diets for obese individuals, including either low carbohydrate (< 130 g/day) or low fat for overall calorie restriction, a diet consisting of low saturated fat ($< 7\%$ of total calories), a minimum of trans fats intake, and < 130 g/day of carbohydrates for all diabetic individuals [18]. An exercise program may have beneficial effects on glucose intolerance, blood pressure control, weight control, lipid profile, and cardiovascular status [3]. Physical activity improves insulin sensitivity by stimulating noninsulin-dependent muscle glucose uptake and increasing substrate oxidation by increasing mitochondrial biogenesis [20, 21] as well as it improves glucose intolerance in diabetic subjects [22]; however, this too should be individualized in elderly patients based on functional status [18].

Medical management and therapeutic options are also similar to the options available in younger individuals. Currently, a number of oral medications are available for the management of older adults with diabetes (Table 39.2). Sulfonylurea drugs are the most widely used. They act initially by increasing pancreatic insulin secretion and later enhance insulin sensitivity, probably via a postreceptor mechanism [23]. Hypoglycemia is the main side effect associated with sulfonylurea drugs.

TABLE 39.2 Currently available oral hypoglycemic agents

Drug	Mechanism of action
Sulfonylureas	Enhances insulin secretion
Second generation	
Glimepiride	
Glipizide, sustained release	
Glyburide	
Glyburide, micronized	
Glimepiride	
α -Glucosidase inhibitor	Slows colonic carbohydrate absorption
Acarbose	
Miglitol	
Biguanide	Decreases hepatic glucose production; improves insulin sensitivity
Metformin	
Thiazolidinedione	Enhances muscle insulin sensitivity
Rosiglitazone	
Pioglitazone	
Nonsulfonylurea	Stimulates insulin secretion
Repaglinide	
Nateglinide	
DPP-4 inhibitor	Prolongs incretin activity
Sitagliptin	

Metformin works primarily by suppressing hepatic glucose production (by suppressing gluconeogenesis) and to a lesser extent by improving insulin sensitivity [24]. Metformin may result in loss of appetite and weight loss, a desirable side effect in obese diabetics. It should be avoided in persons over 80 years of age and should not be used in individuals with either renal insufficiency or heart failure.

The thiazolidinediones (TZDs) is the most recently introduced group of oral antidiabetic agents [25]. These agents function as ligands for nuclear receptor transcription factors (PPAR γ) that regulate genes involved in lipid metabolism and homeostasis. PPAR γ is preferentially expressed in adipose tissue. Activation of PPAR γ leads to adipocyte differentiation and improved insulin signaling of mature adipocytes. Although the main target for action of the TZDs is adipose tissue, their main effect in type 2 diabetes appears to be primarily by enhancing muscle insulin sensitivity [26]. This paradox may be explained by the mechanism of action of TZDs, which are fat cell proliferators and thus by creating more fat cells may act by redistribution of fat from the intramyocellular compartment into fat cells by providing extra storage depots [27]. Muscle insulin resistance in type 2 diabetes (and obesity) is likely caused by intramyocellular accumulation of lipids (certain fatty acids such as diacylglycerol and fatty acyl CoAs), which block intracellular insulin signaling and cause muscle insulin resistance [9, 10]. The TZDs (rosiglitazone and pioglitazone) may be used alone or in combination with other types of antidiabetic drugs such as metformin or sulfonylureas as

well as insulin. The combination of TZDs and metformin for the first time allows for direct targeting of the major pathological defects in type 2 diabetes, reducing hepatic glucose production and increasing muscle insulin sensitivity (stimulating postprandial muscle glucose uptake). The TZDs are generally well tolerated but can, however, cause fluid retention and are therefore contraindicated in patients with class III and IV heart failure [18]. A review of the studies of rosiglitazone led the FDA to conclude that this medication might increase the risk of heart attacks and angina [28], but left the association as inconclusive [29]. Additionally, there is not enough evidence that the risk of heart attack and angina is any greater with rosiglitazone than with other oral medicines used in the treatment of diabetes. Since troglitazone, the first generation of TZDs, was associated with liver injury, that liver enzymes must be measured before starting therapy and periodically thereafter [30].

As type 2 diabetes progresses in older persons adequate glycemic control is associated with an increased risk of adverse effects as a result of age-related changes in drug metabolism. Recently, incretin therapy has become available as novel oral antihyperglycemic treatment, which may prove significant in older persons [31, 32]. Incretins are gut hormones secreted from enteroendocrine cells into the blood within minutes after eating. The two main categories of incretin therapy currently available are: glucagon-like peptide-1 (GLP-1) analogs and inhibitors of GLP-1 degrading enzyme dipeptidyl peptidase-4 (DPP-4). DPP-4 inhibitors are orally active and they increase endogenous blood levels of active incretins, thus leading to prolonged incretin action. The elevated levels of GLP-1 are thought to be the mechanism underlying their blood glucose-lowering effects. There is accumulating evidence that use of incretin therapy, in particular the DPP-4 inhibitors, could offer significant advantages in older persons. Clinical evidence suggests that the DPP-4 inhibitors vildagliptin and sitagliptin are particularly suitable for frail and debilitated elderly patients because of their excellent tolerability profiles [33]. Importantly, these agents lack the gastrointestinal effects associated with metformin and alpha-glucosidase inhibitors taken alone and have a low risk of hypoglycemia. Specifically, sitagliptin has been approved by the US Food and Drug Administration (FDA) for use with diet and exercise to improve glycemic control in adult patients with type 2 diabetes. In randomized, placebo-controlled trials, sitagliptin provided a good treatment option for patients with type 2 diabetes as a monotherapy, or as an adjunct to metformin or a TZD when treatment with either drug alone provided inadequate glucose control [34]. It is also an alternative therapy for those patients who have contraindications or intolerance to other antidiabetic agents [34].

If oral agents are contraindicated or patients fail to respond, insulin is indicated. Physicians should not refrain from initiating insulin therapy in older diabetic patients

simply because of age, however, insulin use requires that patients or caregivers have functional visual, motor, and cognitive skills. Most elderly diabetics do well on insulin injections [35], but physicians should regularly check the ability of their elderly patients to appropriately use the insulin syringe. As with all elderly diabetic patients the risk of hypoglycemia must be weighed against the benefits of tight glucose control and the realistic reduction of risk from microvascular complications. The short-term risk of hyperglycemia including poor wound healing, dehydration, and hyperglycemic hyperosmolar coma must also fit into this balance making this a decision that the clinician needs to consider carefully and on an individualized basis.

Substantial education and continuously monitoring for the degree of diabetic control and the development of chronic complications is key to the management of elderly diabetics. In addition to home glucose monitoring and regular assessments of glycosylated hemoglobin, ongoing care should include annual eye examinations, monitoring of renal function, and regular foot care [18].

Section V
Oral Cavity, Eyes, Ears, Nose and Throat

Chapter 40 Invited Commentary

Frank E. Lucente

It is an honor to participate in this exciting venture by sharing some thoughts and reflections on the changing attitudes and approaches to the care of our elder patients who present with disorders or symptoms in the ear, nose, oral cavity, throat, and eye. Since the publication of the previous volume of this text in 2001, there have unquestionably been advances in the technical capabilities in all of these areas. However, with the population aged over 65 projected to increase from 39 million in 2009 to 70 million in 2020 and with the elderly currently comprising over 40% of medical specialty care, we have a mandate to include training in all medical and surgical aspects of geriatric care in our programs in undergraduate, graduate, and continuing medical education.

Disorders of the head and neck region are high on the list of geriatric impairments that threaten patients' viability and reduce their quality of life, including hearing loss, dizziness and vertigo, tinnitus, swallowing disorders, nasal respiratory disorders, loss of smell, loss of voice, reduction in vision, and neoplasms of this area. The authors of the following five chapters have done a superb job of discussing the substantive developments and advances in the provision of specialty care to the elderly and presenting many recommendations for care of specific medical issues in the head and neck region. I salute them for their achievements.

Looking back over my 40 year career in clinical otolaryngology, I am grateful for having had the opportunity to observe the advances in care of so many diseases that affect the elderly. In the area of head-and-neck cancer, we have seen the development of the multidisciplinary approach to tumor management with tremendous strides in surgery, radiation oncology, and medical oncology. The post-surgical rehabilitation of the cancer patient has also improved greatly through the introduction of reconstructive regional flaps and other techniques. In the area of otology, we have seen the

development of cochlear implants and other devices and techniques that have restored hearing to thousands of elderly patients to whom we previously had little to offer. The development of functional endoscopic sinus surgery has brought relief to millions of elderly patients suffering from chronic rhinosinusitis. Finally, the incredible growth of the specialty of facial plastic and reconstructive surgery has enabled us to rejuvenate many elderly patients who have a strong desire for improved cosmetic appearance of the face and neck. Of course, these advances have not been without controversy as the profession attempts to balance its capabilities with the community's ability to afford them.

One of the most pressing challenges in this area is to assess the relevance of traditional ethical principles to the provision of compassionate and cost-effective care. We have generally been guided by three traditional ethical principles: *Beneficence*: Do only what is good for the patient but no harm. *Autonomy*: The patient has the right to decide what is best for her/himself. *Justice*: The rights of the individual need to be considered in the light of what is best for society as a whole.

In assessing the relationship between what is best for a single patient and what is best for society, a common challenge in the practice of many geriatric specialties, one confronts the issue of the so-called "technological imperative." This refers to the notion that "everything that can be done must be done." We frequently have to examine the use of procedures in patients with limited life expectancy as well as to assess screening programs that are used to identify diseases that are not likely to be treated because of the age of the patient.

As I look back over a 40-year period in training, practice, teaching, and administration as mentioned above, I am impressed with how our attitudes to care for the elderly have changed. As medical students in 1968, we studied and participated in the care of numerous geriatric patients but the focus was on their specific diseases, rather than on their geriatric status. In 1968, life expectancy for an American man was 67 years and for an American woman it was 74 years. In 2009, life expectancy for the man has increased to almost 76 years and for the woman to almost 81 years. Perhaps more

e-mail: Lucente@aol.com

importantly, US National Center for Health Statistics data show that the average number of years of life remaining for the current 75 year-old man is 11 and for the 75 year-old woman is 13. In other words, people are living significantly past the period in which they are contributing to the tax base that is supporting them and increased longevity has raised many financial and logistical issues.

One of the most critical ethical and socioeconomic challenges in this area relates to access for care for millions of elderly. Although the difficulties that confront physicians and surgeons in dealing with office and hospital costs are undeniable, it is discouraging to read numerous reports of denial of care to those unable to pay. While there are many wealthy elderly patients who can and should pay for their care, there are far more who struggle to pay more than Medicare covers. It is disheartening to hear so many reports of physicians closing their doors to these elderly patients. This is an ironic situation as these same physicians received their salary support from Medicare during their residency and without such support they would have had tremendous financial debts.

There is no easy resolution for this difficult situation. Physicians are bearing the burden of increasing costs of practice, including compliance with new regulations that appropriately focus on safe and expeditious patient care, as well as on HIPAA regulations that propose to protect patient confidentiality. However, at the same time, they are frequently seeing reductions in reimbursement for the best care that they can provide. Even the most well-intentioned and competent physician is stressed to provide cost-effective care to all patients who reach out to him/her.

As we confront the issue of access to care, we might note that even Hippocrates (466–377 B.C.) had some cogent observations. In “Precepts”, Part 6 he wrote, “Sometimes give your services for nothing, calling to mind a previous benefactor or a present satisfaction. And if there be an opportunity of serving one who is a stranger in financial straits, give full assistance to all such. For where there is love of such, there is also love of art. For some patients, though conscious that their condition is perilous, recover their health simply through their contentment with the goodness of the physician” [1].

Another cogent guideline for addressing the ethical issues in geriatric care of the head-and-neck patients is found in the writings of the eighteenth century German philosopher, Immanuel Kant. His 1785 publication, *Groundwork of the Metaphysics of Morals* included his articulation of the “categorical imperative” in which he states, “Act only according to the maxim whereby you can at the same time will that it should become a universal law” [2]. If we were to follow his advice, we might view our work with our elderly patients in a different light and find it easier to cope with the challenges posed by the geriatric community.

Chapter 41

Changes in the Oral Cavity with Age

Susan Pugliese and Ajay R. Kashi

Alterations in oral motor functions in aging

Parameter	Changes with age
Lip posture	Drooling, angular cheilosis
Muscles of mastication	Efficiency of mastication
Tongue function	Speech, dysphagia, traumatic bite injury, snoring, sleep apnea
Swallowing	Dysphagia, regurgitation, choking
Taste	Dysgeusia, ageusia
Salivation	No significant changes in healthy older patients

Introduction

Oral health and its implications to one's overall health is often overlooked as insignificant or unimportant by the general population as well as the ever increasing geriatric population. The condition of the anatomical structures in the oral cavity (e.g., tongue, palate, teeth, and gums) can reflect the general health status of an individual. Although many pathologies alter the normal flora of the oral cavity in all age groups, older individuals typically present with certain changes in their oral cavity which are normal for their age [1]. Physicians and dental practitioners must be aware of pathologic findings versus normal findings in the oral cavity that are consistent with aging. Oral changes in the geriatric population have widespread implications ranging from the physical to the psychological and social well being of the individual.

It has been reported, for example, that the general prevalence of oral mucosal disease increases in the elderly population [2]. Pre-existing systemic conditions and changes in the oral cavity can influence surgical procedures and treatment outcomes in this age group. Elective surgical procedures typically require a thorough knowledge of the patients' current

medical status and the past medical history. The oral health status should be a vital part of the overall preoperative assessment of the geriatric general surgical patient. The inclusion of the oral status evaluation would in many cases prevent preoperative, intraoperative, and post operative delays and complications. This chapter discusses changes seen in the oral cavity of the geriatric sub-population. It is well documented that the geriatric population is growing in number. In the United States, people are living longer with and without chronic ailments requiring surgical intervention. In 1900, 3.1 million people or 4% of the population were 65 years or older; by 2005, this number had increased to 34.3 million people or 12.4% of the population, a tenfold increase in number [1]. In view of these statistics, this chapter is written to highlight and guide the general surgeon to some of the most common oral findings and their surgical implications in the geriatric population.

Changes Associated with Aging in the Oral Cavity

The advent of geriatric status in life is associated with changes in the oral cavity including xerostomia, worsening periodontal disease, and oral neoplasms. These changes affect the individual's physical, mental, and social status. For instance, the loss of teeth makes it difficult for communication, thus isolating the individual from his/her usual social environment. An altered motor performance is noticed in older individuals, for example, in lip posture, tongue function, swallowing and masticatory muscle function [3, 4]. Some of the consequences of altered tongue function in older individuals include difficulties in speech, dysphagia, traumatic bite injury, and nocturnal mouth breathing that can lead to a form of sleep apnea. Further, authors have previously reported that difficulty in swallowing can lead to laryngeal food penetration, regurgitation, and sometimes fatal choking [3]. These previously mentioned symptoms need to be taken into account before planning surgical procedures in the elderly.

A comprehensive oral examination performed prior to any surgical procedure(s) in geriatric patients can help to minimize

e-mail: susan.pugliese@downstate.edu

complications during the surgery and the post-operative recovery period (this will also minimize the chances for aspiration, choking, hemorrhage, and regurgitation). In a study by Meurman et al. [5], it was reported that the majority of elderly individuals (~70% of 191; age range from 67 to 96 years) living at home before hospitalization showed dentogenic infection foci as evident from panoramic X-rays, although their infections did not correlate with infection parameters of blood. It was also noted from this study that the majority (96%) of dentate individuals had a poor periodontal condition, and edentulous individuals had positive yeast counts when compared to dentate individuals (84.4% vs. 66.1%, $P < 0.05$) [5].

Tooth mobility, if left untreated, can lead to periodontal pocket formation between the tooth surface and gingival tissues. Further, this can lead to food accumulation and subsequent colonization by bacteria causing localized infection with the potential for wider systemic infections (e.g., cardiac valvular disease from oral bacterial colonization). The oral mucosa becomes more sensitive to mechanical damage as age progresses [6]. This may lead to easy bruising, either from minimal trauma (e.g., from sharp edges of denture margins) or nutritional deficiencies. Furthermore, it is also important to note that easy bruising of tissues can delay post-operative wound healing, thus emphasizing the need to take steps to minimize trauma during any surgical procedure. Missing teeth, dry mouth, and ill-fitting dentures can lead to a lack of social interaction in the elderly. If treatments to these underlying causes are not provided, it can lead to a severe lack of confidence and depression. Some of the common changes seen in the oral cavity of elderly patients are presented in the physiology table at the opening of this chapter [7].

Oral Manifestations of Systemic Disorders

Systemic diseases that most commonly affect older adults in the developed world are arthritis, cancer, chronic obstructive pulmonary diseases, diabetes, heart disease, hypertension, mental health conditions, osteoporosis, Parkinson's disease, and stroke [1]. Oral manifestations of systemic disorders and the drugs used to treat them can influence surgical treatments in the elderly. Further explanation of some of the commonly encountered systemic disorders and their consequences on treatment decisions is discussed.

Musculoskeletal Disorders: Osteoarthritis, Rheumatoid Arthritis, Osteoporosis

According to the World Health Organization, osteoarthritis will become the fourth leading cause of disability worldwide by 2020 [8]. Authors have reported that the strongest risk

factor for osteoarthritis is age [9]. Some of the other risk factors include an increase in body weight, mechanical trauma, and laxity of the surrounding ligaments. It has been reported that almost half of the population older than 65 years of age suffers from arthritis [1]. One of the major reasons for the progression of osteoarthritis is the inability or decreased ability of the damaged cartilage to repair following injury. Secondary effects of osteoarthritis in the hands include difficulty in maintaining oral hygiene as a consequence of pain and impaired functional ability. This can lead to increased incidence of dental caries and periodontal disease in the elderly. Poor periodontal health is also known to contribute toward higher chances of systemic infections, thus having the potential for post-operative complications.

Presence of pain and lack of mobility can prevent people with osteoarthritis from visiting their dentist for routine oral healthcare. Most likely, a patient with arthritis or other musculoskeletal disorder will be consuming one or more medications to treat their illness. Typically, this can include pain killers, muscle relaxants, and drugs that prevent bone loss. Dental considerations in patients with musculoskeletal disorders range from the appropriate selection of drugs to helping patients with their oral hygiene needs. Simple steps including designing toothbrushes with large handles or encouraging patients to use electric toothbrushes can be beneficial in maintaining oral health. It has been reported that before invasive surgical procedures, corticosteroids and antibiotics need to be considered in elderly patients [1]. However, these drugs should be used with caution due to their systemic effects in the elderly.

Another important and common musculoskeletal disorder that affects the elderly includes osteoporosis. Dental considerations in osteoporosis include anecdotal reports of a side effect from the introduction of a recent class of drugs known as bisphosphonates to treat osteoporosis. These side effects include osteonecrosis of the lower jaw in some patients who are consuming this class of drugs and have undergone invasive dental procedures, although this clinical symptom has been reported to be more common in patients who are being treated for malignant diseases and who have received high-dose intravenous bisphosphonate therapy [10–12]. The exact mechanism that is responsible for the osteonecrosis seen in the jaws is yet to be ascertained and further clinical investigations and research needs to be carried out to better understand this important side effect. Before planning surgical procedures in elderly patients, it is important to consider the side effects and/or other drug interactions if patients are using this drug.

Cardiovascular Disease and Oral Health in the Elderly

Coronary heart disease was and remains the most likely cause of death in the geriatric population in the USA [1].

Oral health is correlated with initiation and/or progression of many cardiovascular pathologies (e.g., infective endocarditis), along with other factors. Poor periodontal health is one of the reasons for loss of teeth in the geriatric population, and for the colonization of oral pathogens on cardiac valves. Several etiologic factors including family history, lack of exercise, high cholesterol, smoking, and genetic factors contribute to cardiovascular disease. From a perspective of dentistry, people with fewer teeth generally prefer chewy foods including red meat and cakes, and avoid crunchy foods (e.g., carrots and dry breads) [13]. Further, high calorie, high fat foods can lead to higher chances of obesity and coronary heart disease in this population segment. Thus, it can be inferred that tooth loss, while not directly related to cardiovascular disease, has a significant secondary effect in terms of leading to cardiovascular disease (i.e., by choosing foods that are high in fat content). From a general surgical perspective, it is essential to be aware of the patient's general systemic health including their cardiac condition. Basic diagnostic tests including blood pressure, EKG recordings, and chest X-rays should be routine practice before invasive dental and surgical procedures are carried out in the elderly. Patients with certain cardiovascular conditions are typically required to take antibiotics prescribed by the American Heart Association and/or the American Dental Association before invasive dental procedures (e.g., deep scaling of roots, tooth extractions, periodontal/oral surgical procedures) [2, 3]. The complete list of medications including the recommended dosage and regime(s) is available from the published literature [14, 15]. Wilson et al. [15] advocate improved access to dental care and oral health in patients with underlying cardiac conditions that may be associated with increased risk of adverse outcomes from infective endocarditis (e.g., valvular heart disease). This will help to minimize the chance of infection in the surgical patient.

Diabetes and the Oral Cavity in the Elderly

There are more than 20 million individuals affected by diabetes mellitus in the USA [16]. The incidence of adult-onset (Type II) type of diabetes is more prevalent in people over the age of 50 years. The oral cavity is often reflective of signs suggestive of diabetes mellitus, some of which include multiple periodontal abscesses and slower wound healing following extractions or other oral surgical procedures. Full-mouth intra-oral periapical radiographs will usually reveal the presence of multiple periodontal abscesses in the diabetic patient. Furthermore, other soft tissue condition including candidiasis is more prevalent in the oral cavity of diabetics with poor glycemic control and denture use [16]. It is mandatory that blood sugar levels be determined before any invasive surgical procedure(s) in the elderly as it can

directly affect the duration of post-operative healing in addition to helping prevent complications (e.g., post-operative wound infections).

Mental Health Conditions and the Oral Cavity in the Elderly

Mental disorders constitute a range of serious illnesses. Among them, some of the important ones that warrant discussion include Alzheimer's and Parkinson's disease as these conditions mostly affect the elderly.

Alzheimer's Disease

Alzheimer's disease mostly affects the elderly population. It is the most common type of dementia and was first described by Alois Alzheimer in 1907. The incidence of Alzheimer's includes approximately 10% of older adults over 65 years of age and 45% over 85 years of age; the prevalence of this disease is expected to double by 2020 given the aging population in the USA [17, 18]. The cause of Alzheimer's remains unknown, although there are some reports implicating the loss of cholinergic neurons. Risk factors can include age, family history of dementia, and the presence of both ApoE4 alleles. Table 41.1 describes the signs and symptoms of Alzheimer's disease and the recommended dental management.

It has been reported that one-half of all patients with Alzheimer's need help with their personal care, and one third are eventually hospitalized [17]. Friedlander et al., mention that an inability to perform appropriate oral hygiene practices mainly results from impaired cognition, apraxia, and apathy in the middle stages of the disease. The authors also mention that there can be marked hyposalivation in these patients, especially localized to the submandibular salivary gland, and this can lead to symptoms of xerostomia [17]. The aim of dental treatment in Alzheimer's disease is to provide a realistic or meaningful solution to the patient's problems that can influence their quality of life positively. Simple procedures including taking care of sharp or jagged tooth/teeth and dentures can be more important initially than restoring carious teeth, as this might arouse intense anxiety in Alzheimer's patients. Complex dental procedures including tooth extractions and restorative dental procedures need to be carefully planned in such patients.

Several drugs that are routinely used in dentistry have been known to interact with drugs used to treat Alzheimer's. For instance, Alzheimer's drugs including Aricept (Donepezil), Razadyne (Galantamine), and Exelon (Rivastigmine) have been known to interact with non-steroidal anti-inflammatory drugs (NSAIDs) by increasing the chances for gastrointestinal

TABLE 41.1 Stages of Alzheimer's disease, signs, symptoms and dental considerations

Disease stage	Signs and symptoms	Dental findings	Dental management
Early stage	Reduced ability to follow instructions on the job, driving, shopping and housekeeping; require constant reminders	Changes in the oral cavity (e.g., coronal and root caries, plaque buildup) can be seen if the patient is unable to remember routine activities including maintenance of oral hygiene (i.e., brushing and flossing)	Routine dental treatment can be provided in most patients, aggressive preventive dentistry program (e.g., 3 month recall, oral examinations, prophylaxis, fluoride gel application, adjustment of prostheses)
Middle stage	Inability to work, easy to get confused, language impairment including comprehension and naming of objects, inability to do simple calculations, to tell time and loss of simple motor skills such as eating, dressing and solving simple puzzles; requires daily supervision	High incidence of xerostomia from antipsychotic medications, dry mouth, mucosal lesions, candidiasis, plaque and calculus buildup, periodontal disease, root caries, and high chances for aspiration pneumonia	Main focus of treatment should include maintaining dental status and minimizing deterioration, aggressive preventive dentistry program
Advanced stage	Patients may become rigid, incontinent, bedridden, present with generalized seizures; often require nursing care and supervision	High incidence of xerostomia from antipsychotic medications, dry mouth, mucosal lesions, candidiasis, plaque and calculus buildup, periodontal disease, root caries and high chances for aspiration pneumonia	Short appointments, non complex procedures; sedation (e.g., benzodiazepines) can be used for complex and tedious dental procedures, aggressive preventive dentistry program

(GI) bleeding and irritation. Other commonly used drugs in dentistry (e.g., Aspirin, Codeine, Clarithromycin, Erythromycin, and Opioid analgesics) have been reported to interact with drugs that are used to treat Alzheimer's disease [17]. It is best for the dentist to consult with the patient's physician to determine the level of cognition and ability to provide consent, to get information related to other underlying medical conditions (e.g., heart disease, diabetes, hypertension), and to complete a drug history before providing dental treatment and certifying that the patient is fit to undergo general surgical procedures.

Stroke

Stroke is the acute onset of neurological deficits persisting for at least 24 h. Two thirds of strokes occur in people over the age of 65 years and about 8% of the US population above 65 years of age has a history of stroke [1, 19]. Stroke or cerebrovascular accident is a serious medical condition that can have adverse effects on an individual's overall systemic health. The primary effects of these diseases might not be visible in the oral cavity, although they can have secondary effects in terms of deterioration of oral health status because of an inability to maintain oral health. This is mostly observed on the side of the face affected by stroke, as the individual lacks manual dexterity to maneuver the oral cleansing devices to clean their teeth. Some of the specific changes that can be seen in the oral cavity include halitosis, tooth decay, root caries, gingivitis, periodontal infections, and fungal infections (e.g., candidiasis). It is very important to emphasize that

FIGURE 41.1 Root caries, partial edentulism, and gingival recession in an elderly patient.

patients with these diseases need special attention for their oral healthcare needs. MacDonald mentions that the incidence of root caries increases almost eightfold in patients with neurodegenerative disorders when compared to others living within the same community (Fig. 41.1) [20].

The dental professional will have to differentiate between a true deterioration of oral health (from a conscious lack of maintenance of oral health) and secondary oral health effects from an underlying illness (e.g., stroke, Alzheimer's). In the former scenario, patient education might work to reverse poor oral health, whereas the latter case will need special care in terms of assistance to care for an individual's oral health. During dental treatment, it is especially important in patients with stroke to ensure that foreign bodies are not

aspirated into the pharynx as they might lack sensation on a particular side of their body and hence not have a normal gag reflex. Simple steps including talking to the patient slowly and not using complex language can be helpful. In addition, it is better to schedule dental appointments during the mid-morning in these patients [1]. It is important to note that elective and invasive dental procedures are generally deferred for a period of about 3 months following a stroke. This needs to be considered in a surgical treatment protocol, where the surgeon might need the patient to have dental treatment prior to a planned surgery.

Nutritional Status and Dental Health in the Elderly

The nutritional status of elderly individuals is often compromised when compared to their younger counterparts due to a variety of reasons, including a higher incidence of systemic illnesses (e.g., diabetes) and medications that suppress the immune system. The overall nutritional status of an individual depends on a number of factors. For instance, it is known that gastrointestinal motility/health can be maintained with fiber in the diet and it has been reported that the presence of teeth will help with fiber intake [21]. However, it can be challenging for edentulous patients to chew fibrous foods, thus leading to higher chances of an imbalance in their general systemic health. Softening of foods (e.g., vegetables and fruits to assist with chewing in edentulous patients) can lead to denaturation of important nutrients including Vitamin C. In the long-term, this can lead to systemic illnesses including scurvy. Thus, Vitamin C deficiency can be correlated to the number of teeth present in the oral cavity. It has also been reported that Vitamin C remains one of the key nutrients that are missing in edentulous elderly individuals [21]. Figure 41.2 shows the oral cavity of a malnourished female patient, aged 78 years with a medical history of hypertension, dysphagia, diabetes mellitus, and psychiatric symptoms including depression and dementia. In addition to pain, she was unable to eat due to chronic periodontal disease and tooth mobility.

Edentulous conditions, when coupled with poor nutrition can have other consequences including bone resorption (more rapidly in the mandible when compared to the maxilla) (Fig. 41.3). This makes it difficult to fabricate stable mandibular dentures. Studies have shown that edentulous elderly patients generally consume less nutritious foods, particularly less protein, intrinsic and milk sugars, calcium, non-heme iron, niacin, and Vitamin C when compared to dentate people [21]. In order to improve wound healing following surgery, it is important to include nutritional supplements (e.g., multivitamin tablets, medications to improve the

FIGURE 41.2 Oral cavity of a 78-year-old malnourished female patient. Note the poor periodontal condition of the teeth.

FIGURE 41.3 Complete edentulism of mandibular arch with resorption of the alveolar ridge in an elderly patient.

hemoglobin content of the blood) in the diets of the elderly. It must also be noted that a balanced diet tailored to elderly patients based on their chewing capability needs to be ensured post-operatively.

Aspiration Pneumonia

Aspiration pneumonia deserves special discussion because of the high chance of infection of the lungs from aspiration of oral contents and/or foreign objects in the geriatric population. This can occur as a result of higher incidence of dysphagia, stroke, and other neurological disorders in the geriatric surgical patient. Another important etiology for aspiration pneumonia includes accidental avulsion and aspiration of teeth from anesthetic intubation procedures during the pre-operative surgical preparation. Possible routes of

entry for the avulsed teeth can include the trachea to enter the lungs or the esophagus to enter the stomach. Appropriate emergency measures including locating the tooth/teeth from chest or abdominal X-rays and their aspiration or surgical removal must be performed immediately. This is especially important in elderly patients to avoid pneumonia.

Aspiration pneumonia can lead to serious complications in elderly patients due to reduced ability to cope with illness from a higher likelihood of being immunocompromised. From a surgical perspective, it is important to note that aspiration pneumonia can lead to serious complications post-operatively (for instance, during the recovery period), and aspiration of oral contents including dried salivary debris has been known to cause infections and morbidity. One of the most common and often ignored changes (in the oral cavity) in older individuals is increased tooth mobility. Increased tooth mobility (usually associated with periodontal infections) in the elderly is associated with higher mortality as there is a greater chance for aspiration pneumonia.

The relationship between oral health and the mortality from pneumonia in an elderly Japanese population has been studied [22]. In this study, the authors evaluated 697 individuals (277 males and 420 females) who were 80 years old in 1997. The study results were documented between 1998 and 2002, during which 180 of the study patients died. According to their results, the adjusted mortality due to pneumonia was 3.9 times higher in persons with ten or more teeth with a probing depth exceeding 4 mm (periodontal pocket) than in those without periodontal pockets [22]. Some of the other findings reported from this study indicate that the number of *Candida* species on the lingual surface was much higher in those who died of pneumonia when compared to other participants [22]. This may be attributed to the possibility of an immunocompromised state in this age group, leading to resistance against virulent bacteria (mostly anaerobic gram-negative bacteria) and subsequent colonization by opportunistic pathogens including *Candida*.

Saliva

Diminished reserve capacity of individual organs (e.g., kidneys, gut, respiratory, and salivary glands) is an age-dependent phenomenon [23–25]. A loss of acinar cells of the salivary glands takes place with age although the salivary flow rate is maintained [23, 26, 27]. These findings might not have any adverse consequences during normal function, but they can become important in situations common to surgical patients: during physiologically stressful circumstances including surgery, with disease, and with intake of pharmacologic agents (e.g., anticholinergic drugs) that can compro-

mise the reserve capacity of salivary glands [23]. Reduced salivary volume can lead to a compromise of its rheological properties and consequent decrease in its ability to moisten the oral cavity and teeth. This can be a predisposing/contributing factor for rapid rise in the incidence of dental caries, infections and dry mouth.

Xerostomia

Xerostomia is also commonly known as “dry mouth.” Although xerostomia can manifest at any age, it has been reported that this symptom is especially prevalent in the elderly population, particularly over the age of 65 years [28, 29]. Some authors suggest that approximately 25–30% of the population over the age of 65 years is affected by complaints of dry mouth [29, 30]. The sensation of dry mouth in the elderly is related to the use of drugs, radiotherapy, and autoimmune diseases including Sjogren’s syndrome [27]. Among these previously mentioned causes for xerostomia, drugs are known to have significant effects when compared to the other two conditions. Clinicians have suggested causes for xerostomia [28], although the main etiologic factor remains idiopathic in nature. A reduction in the number of acini and an increase in the amount of fatty and fibrous tissues as age increases has been reported earlier by investigators [30]. However, Ship and Turner et al., have mentioned that healthy adults (i.e., without any complaints of systemic disease) remain relatively free from complaints of dry mouth [28, 29, 31].

Xerostomia needs to be considered as a significant clinical complaint in the elderly because of its potential to affect an individual’s daily activities. Thus, this clinical symptom needs to be given consideration in the overall treatment plan in the geriatric surgical patient. For instance, daily activities including wearing of dentures can be painful in patients with xerostomia. Furthermore, speaking and eating certain types of foods can also be a challenge in patients with xerostomia; this can also lead to psychological effects on the individual including a lack of social interaction [32].

Oral Mucosal Lesions in the Elderly

It is common to encounter mucosal lesions in the elderly, as the general immune response and healing capability of geriatric patients are poorer when compared to their younger counterparts. Aggressive treatment including patient education must be emphasized to treat and prevent oral mucosal lesions in the elderly, as this can also affect the general

TABLE 41.2 Oral mucous membrane lesions in the elderly

Problem	Cause	Treatment
Mucositis/glossitis	Systemic disease (e.g., diabetes, hematologic disease/anemia/leukemia, chronic mouth breathing) Nutritional deficiencies (especially Vit B complexes) Adverse drug reactions (e.g., aspirin, antibiotics, phenacetin)	Complete blood count and Vit B ₁₂ evaluation Rule out xerostomia Palliative mouthwash prescription, diphenhydramine (Benadryl)/kaolin (Kaopectate) in equal parts, 1-min rinse, then expectorate; or lidocaine (Xylocaïne viscous) 2%
Infection from immunosuppression Candidiasis	Systemic disease (diabetes, leukemia) xerostomia Immunosuppression (prolonged steroid use) antibiotic or antineoplastic medications, ill-fitting prostheses	Improved oral hygiene Antifungal medications

systemic health and surgical treatment decisions. A list of some of the commonly seen oral mucosal lesions in the elderly is shown in Table 41.2.

The incidence of oral neoplasms also increases with age. Some of the common etiological factors include a history of smoking, drinking, chewing tobacco, and genetic factors. It is important to note that many neoplasms are initially noticed in the oral cavity and can be an evidence of metastasis from other sites. Often, these tumors require dissection that can be disfiguring and alter oral function, thus affecting the general systemic health as well as the psychological state of the geriatric patient.

FIGURE 41.4 Oral candidiasis in a 58-year-old male operated for removal of squamous cell carcinoma of the palate. This patient was undergoing post-operative radiotherapy of the jaws along with chemotherapy.

Opportunistic Infections

Opportunistic infections are quite common because of underlying factors including higher rates of systemic illnesses (e.g., diabetes) and a suppressed immune system in the geriatric population. Some of the commonly seen opportunistic infections in the oral cavity include candidiasis and oral manifestations of human immunodeficiency virus (HIV).

Candidiasis

In the United States, the three most common reasons for referrals by general dentists of older adults with oral mucosal lesions are suspected malignant lesions, inflammatory vesicular lesions and candidiasis [33, 34]. Candidal infection is an extremely common and often unnoticed condition in the geriatric general surgical patient (Fig. 41.4). Oral candidiasis is commonly encountered among denture wearers, in debilitation, diabetes, anemia, in those receiving chemotherapy or local irradiation, in patients consuming corticosteroids, or broad-spectrum antibiotics, and smoking [14, 35].

It is also seen as a manifestation of other serious illnesses including HIV.

The fungus responsible for candidal infections is a normal part of the oral flora. It is overgrowth of these organisms (mostly due to a suppressed immune state) that leads to pathology which is often manifested by white, red, or white and red surface changes. It often appears under a denture as an acutely inflamed area in the exact shape of the denture or as white cheese like lesions that can be removed with a tongue blade. Candidiasis can be painful along with symptoms of halitosis and alterations in taste (dysgeusia). It occurs frequently due to improper denture use and maintenance, thus making it hard to diagnose and treat this condition effectively. There is a high likelihood that patients are unaware that they have this condition, although it can be long standing. In severe cases, it can be erosive and quite painful. Motor and cognitive skills are often diminished in the geriatric population, thus making it difficult to treat oral candidiasis as the treatments might require active participation on the patient's part.

CASE STUDY

A 58-year-old male patient that was referred to the dental clinic following surgery of the maxilla and palate for resection of squamous cell carcinoma is described. The tumor had invaded the left portion of the maxilla, hard and soft palates, left pterygomaxillary space, and the wall of the maxillary sinus. The patient's personal history included smoking for a period of 33 years and drinking, while his medical history included anemia and hypertension. He was operated for removal of the tumor mass, following which he was receiving radiation and chemotherapy. A communication between the palate and the maxillary sinus was present from the surgical procedure (Fig 41.4). This patient was referred to the dental clinic for an oral examination and rehabilitation of his oral cavity. During the oral examination, white patchy discoloration was observed, mainly on the upper borders of the maxillary arch and palatal regions (Fig. 41.4); a clinical diagnosis of candidal infection was made. Clinical diagnosis of candidal infection(s) can be confirmed with a smear or culture [34]. The clinical

FIGURE 41.5 Maxillary denture incorporating the obturator to seal the communication between the oral cavity and orbit for speech and nutrition in a 58-year-old patient operated for removal of a tumor.

management of this patient included immediate and aggressive treatment of his candidal infection, fabrication of an obturator (Fig. 41.5) to close the communication between the oral cavity and the nasal cavity, educating the patient about denture care and the importance of maintaining oral hygiene.

Further, in patients with complicated medical/surgical histories, it is important to address systemic symptoms when providing treatment for the dental symptoms. For instance, radiation and chemotherapy will have the potential to further suppress the immune system in these patients, and hence, recurrent fungal infections including candidiasis are more prevalent in these individuals. Routine dental checkups are vital to ensure that the oral cavity is free from infection. The patient's physician should be part of the decision making team along with the dentist to provide the best available treatment.

It is important to note that the most common causes of a candidal overgrowth leading to infection are hyposalivation, high blood and salivary glucose, immune suppression, and the use of corticosteroids and antibiotics. Immunosuppressed patients are particularly predisposed to systemic, invasive infections of candidiasis. The gastrointestinal tract, trachea, lungs, liver, kidneys, and central nervous system are all potential sites for infection in disseminated systemic candidiasis and may result in septicemia, meningitis, hepatosplenic disease, and endocarditis [4]. It is important to identify the primary cause (whether it is denture related, drug related, or from an immunocompromised systemic state) and extent (local or systemic) of the infection before any treatment recommendations are made. In the case of localized infections, it is essential that the oral cavity be treated first to prevent recontamination of the tissues by the denture.

Treatment of oral candidiasis can be topical or systemic. The clinician might choose one mode over the other best treatment option based on the location and extent of the infection or immune status of the patient. Topical treatment generally includes Nystatin oral suspension: 100,000 U/ml, 5 cc swish and spit or swish and swallow (if pharyngeal involvement is suspected) for 14 days. This should be performed after meals and before going to bed. An alternative topical treatment for oral candidiasis is Clotrimazole troches, 10 mg, dissolved in the mouth five times a day for 14 days, taking care not to eat or drink for half an hour after ingestion. Systemic treatment for *Candida* includes either of the following antifungal medications: Nizoral (Ketoconazole) tablets, 200 mg, once daily with meal for 14 days, Diflucan (Fluconazole) tablets, 100 mg, two tablets stat followed by one tablet daily for 14 days, or Sporanox (Itraconazole) tablets, 100 mg, twice daily with meals for 14 days.

Oral hygiene and denture hygiene are essential to the resolution of the candidal infection. Simple steps including reminding patients never to sleep with dentures in their mouths (this gives the tissue in the oral cavity time for aeration) can be helpful in preventing future infections. The dentures should be thoroughly cleaned daily by soaking them in 1% sodium hypochlorite solution for 15 min followed by rinsing with running water for 2 min before sleeping [36]. It is prior to surgery that the geriatric patients may not be as capable cognitively and physiologically of responding to a

fungal infection. Thus, it becomes essential that treatment be thorough and complete prior to surgery. This will prevent post operative complications and the possibility of an overwhelming systemic candidal infection.

Human Immunodeficiency Virus

The general surgeon will encounter a greater number of geriatric patients with HIV, either those newly infected or those with the virus as a chronic illness (the benefit of highly active antiretroviral therapy, or HAART). Furthermore, it has long been recognized that patients with HIV or AIDS will at some point in their disease progression or its chronic state exhibit one or more oral manifestations of the disease. It has been reported that as many as 90% of individuals with AIDS will eventually experience one or more oral lesions [37]. The presence of an oral lesion in the HIV patient can be an indicator of a high viral load or failing drug therapy that may need to be addressed prior to surgery. The surgeon should be aware of the more common oral manifestations of HIV/AIDS, as their presence may affect the general health of the patient and the surgical outcome of a procedure that the patient may be undergoing.

Some of the common oral manifestations of HIV/AIDS infection include oral candidiasis, hairy leukoplakia, angular cheilitis, recurrent aphthous ulcers, gingival disease, warts/condylomas, Kaposi's sarcoma, herpes, xerostomia, and salivary gland disease. Oral lesions can act as a conduit for the spread of infection and further compromise the immune function in AIDS patients, thus accelerating disease progression and death [38]. Thus, it is critical for the surgeon to look for these signs and symptoms, as they may affect his/her surgical treatment decision. The transmission of the virus seems to be somewhat different in the geriatric population when compared to the general population. The major etiologic factor for AIDS cases with advancing age include blood and blood product transfusion rather than homosexual contact and intravenous substance abuse [39].

HIV/AIDS in the geriatric population seems to take on new and challenging diagnostic and clinical characteristics, as many of the diseases or conditions associated with aging can lead to misdiagnosis and delay of appropriate treatment. Elderly patients are at an increased risk for contracting other infections when there is a diagnosis of HIV/AIDS already, thus highlighting its importance in surgical practice [40]. Ship and Wolff mention that the geriatric patient with HIV is at increased risk for developing other infections as the immune system declines in function as a result of the aging process [39].

The increasing prevalence of HIV infection in our general and geriatric population makes it important to include oral examination in the preoperative evaluation of patients. Often,

oral lesions are noted as the first indication of HIV/AIDS. In the initial stages of the disease, the viral count may be high and the CD4 count may be under 200, thus increasing the likelihood of the presence of one or more oral manifestations in an HIV infected individual. The presence of an oral lesion can raise the suspicion of the practitioner to investigate further to reach an accurate diagnosis and/or treatment of undiagnosed HIV infection. It is common to find HIV patients with altered hemoglobin B/hematocrit (Hgb/HCT), white blood cell (WBC), absolute leukocyte count (ALC), absolute neutrophil count (ANC), and platelet counts. These findings can lead to higher incidence of intraoperative hemorrhage and postoperative infections [41]. Thus, an accurate diagnosis has a huge impact on intraoperative and post-operative surgical outcomes.

Elderly patients generally have declining social and cognitive skills and might often be incapable of reporting signs and symptoms that are a consequence of HIV/AIDS infections. This can lead to undiagnosed infections for long times and affect the health of the geriatric patient. It is vital for the physician/surgeon to be aware of the possibility of HIV infection in their patients and they must be trained to identify this disease and/or its symptoms prior to performing surgery. This process must include a review and evaluation of all the systems, including the oral cavity. The dentist and the general surgeon must consult with each other to make the preoperative evaluation of the geriatric patient accurate and complete to ensure acceptable surgical outcomes.

Surgical Considerations in the Geriatric Population

Normally, slower rates of wound healing and longer recovery times after surgical procedures can be expected to occur in the geriatric population. As mentioned previously, the oral mucosa becomes more sensitive to mechanical damage as age progresses [6]. Thus, it is important that surgical procedures be performed as non-invasively as possible in the elderly. In addition, other factors need to be carefully considered before embarking on surgical procedures in elderly patients. For instance, relying entirely on blood parameters of infection might not be sufficient to assume that the patient may not harbor a risk for a post-operative infection. The presence of dentogenic infection foci can be a positive finding regardless of a lack of infection parameters of blood. This might contribute to post-operative infections as the patients are generally under stress during the recovery phase of the surgery. Thus, it is highly recommended that physicians/surgeons refer geriatric patients for a complete oral health check-up before planned surgery. Oral sensorial complaints are more prevalent in elderly people who take

TABLE 41.3 Pre-operative dental evaluation in geriatric surgical patients

Structure	Examination	Findings	Surgical implications
Hard tissue(s)	Review of X-rays with probing of tooth surfaces	Cariou lesions – thinning of enamel, tooth erosion	Pre and post-operative bacteremia
	Full mouth series	Narrowing of the pulp chamber	Avulsion of teeth during anesthetic administration
	Panorex baseline for relationship between mandible and maxilla	Neoplasms (e.g., cotton wool appearance)	Complicated post-operative course
		Bone cysts (traumatic and pathologic)	
		Osteonecrosis	
		Previous fractures	
		Pathological fractures	
	Documentation of carious lesions (both clinical and radiographic)	Deep lesions may penetrate the pulp chamber	Pre and post-operative infection
	Periodontal bone loss (vertical and horizontal); severity	Vertical and horizontal bone loss	Aspiration of loose teeth
	Tooth mobility	Bone spurs and bone lesions	
	Abrasion, erosion, attrition	Periodontal pockets and inflammation	Can affect intubation techniques and post-operative infections
Soft tissue(s)	Visual examination of hard and soft palate, oropharynx, tongue (dorsal, ventral, and lateral), lip, floor of mouth, vascularization of oral cavity	Thinning of oral mucosal tissues	Delicate mucosal tissues can be easily traumatized during intubation procedures leading to pain and difficulty when consuming foods
		Soft tissue lesions (benign and malignant)	Distant metastases
	Lymph nodes (intra-submandibular, and extraorally), anterior and posterior cervical nodes, subauricular, pre and post auricular	Can be palpated in inflammatory conditions and neoplasms as hard/indurated masses along the distribution of the lymphatic chain	Could delay surgical procedure(s) because of an active infection or neoplasm
	Gingival recession	Tooth root exposure	Higher chances for bacterial colonization on exposed tooth root surfaces, pre and post-operative complications

pharmaceutical drugs when compared to people who do not [29]. Surgical considerations in elderly patients include pre and post-operative side effects (i.e., Xerostomia, oral ulcers, and sensorial complaints) of drugs used during the surgical procedure in addition to the effects of other drugs that the patient consumes regularly. These side effects can also interfere with other daily activities such as eating, drinking, and talking. Table 41.3 provides a list of examination techniques that are used to determine if the oral tissues show signs of pathology and their surgical implications.

Summary

The components of successful aging are generally considered to be low probability of disease, avoidance of complications of chronic diseases, high functional capacity (both physical and cognitive), and active engagement with life, including interpersonal relationships and productive activity [42]. By the year 2030, the population of America is projected to be around 350 million, and one of every five or roughly 20% of these may be 65 years or older [43]. Lamster mentions that students currently enrolled in dental schools will be within their practice lives by the year 2030, which

highlights the need for emphasizing geriatric dental education in the present curriculum to address needs of this sub-group of people in the future [43]. It has been reported that the average dental practice would be expected to have about 260 or more patients 65 years of age or older [44], thus highlighting the need for dentists to be trained in diagnosing and treating symptoms of illness in the elderly.

Some medical needs of the geriatric sub-population will be different when compared to other sections of society. For example, comorbidities from some pairs of diseases (e.g., arthritis and heart disease), when occurring either alone or at the same time in the elderly can significantly increase the risk of disability. Diseases such as Alzheimer's which mostly affect the elderly might not have any direct effects on the oral cavity, although they can have secondary consequences related to the maintenance of optimum oral health. Psychiatric disorders including depression and medical conditions that interfere with motor skills and coordination (e.g., palsies, cerebrovascular events) can indirectly affect the maintenance of the oral health and general systemic health of elderly patients.

In summary, the clinician must be aware of the following points before surgically treating geriatric patients:

- The surgeon must not rely entirely on blood parameters of infection, but must be trained to look for other sources of infection including dental infection foci

- The surgeon must be aware of the most commonly occurring soft tissue lesions (i.e., oral neoplasms, vesiculoerosive disorders, and candidiasis) in the oral cavity of elderly patients
- It should be mandatory practice for the surgeon to include an oral examination of their patients pre-operatively to minimize post-operative complications
- The incidence of systemic illnesses and their oral manifestations is generally higher in the geriatric population when compared to their younger counterparts. Some of these symptoms include candidal infections from diabetes, immunosuppressed states, lymph node involvement from infections, oral neoplasms, and xerostomia from drug reactions and denture use.

Chapter 42

Geriatric Ophthalmology

Andrew G. Lee and Hilary A. Beaver

CASE STUDY

An 87-year-old woman presents for a new patient exam with blurred vision in both eyes. She and her family feel that her vision has progressively worsened over the last few months, and she can no longer safely drive a car or perform her activities of daily living. They are worried about her ability to continue living alone without assistance. The patient complains that her glasses “don’t seem to work anymore,” and notes that she has had several unexplained falls over the past few weeks. She was last seen by an ophthalmologist 1 year ago. She missed multiple follow up appointments with that ophthalmologist because she “couldn’t get a ride.” She did not pursue therapy with them because they told her the problems were related to “old age,” that she was “too old to have surgery,” and that “nothing could be done” to improve her vision. Her prescription for eye drops has since expired. She feels depressed about her visual loss and anticipates a loss of independence. Her family believes there is a decline in her mental function, and that her dementia symptoms are worsening, and feel she is intermittently depressed.

She has a past medical history of poorly controlled diabetes mellitus, cataract, age-related macular degeneration (ARMD), and chronic open angle glaucoma. She is

on insulin and topical timolol drops in both eyes. She smokes one pack of cigarettes per day and has done so for 50 years. Her family history is significant for diabetes, glaucoma, and macular degeneration.

On examination, her visual acuity is a slow 20/100 OD and 20/80 OS. Her external exam shows dermatochalasis, and her motility is normal. The pupils are normal without a relative afferent pupillary defect. The slit lamp examination shows bilateral nuclear sclerotic cataracts consistent with 20/70 visual acuity. The intraocular pressure is elevated in both eyes at 30 mm Hg, and she states she has not taken her eye drops since her prescription expired; the patient further observes that the drops make her “dizzy” and she is reluctant to restart therapy. The optic nerves show glaucomatous cupping to 0.8 cup to disc ratio bilaterally with an inferior vertical notch in both eyes. The macula shows multiple large macular drusen and mild eccentric geographic atrophy of the retinal pigment epithelium (RPE) consistent with the dry form of ARMD. She has a mild, scattered, dot and blot hemorrhages in the posterior pole consistent with mild non-proliferative diabetic retinopathy. Formal Humphrey Visual Field testing is unreliable OD, and the patient is not interested in completing the testing OS.

Significance of the Problem

The demographic shift towards an older population in the USA is well documented and has been discussed in other chapters in this text. The number of patients older than age 85 years (such as in our case vignette) is projected to double

from 4.7 million in 2003 to 9.6 million in 2030, and by 2050 to 20.9 million. Ophthalmology as a specialty will be disproportionately affected by the demographic shift as the most common causes of chronic visual impairment all show an increased incidence and prevalence in the elderly population. The most common age-related visual problems with geriatric ophthalmic surgery implications are cataracts, glaucoma, diabetic retinopathy, and ARMD. The incidence of cataract dramatically increases with age and half of patients over the age of 75 will develop a visually significant cataract in one or both eyes. One quarter will have the non-exudative or “dry” form of ARMD, 5% will have the exudative or “wet”

e-mail: andrew-lee@uiowa.edu

form of ARMD, and 2–10% will have glaucoma [1–5]. In addition, many other blinding disorders (e.g., giant cell arteritis, non-arteritic anterior ischemic optic neuropathy, cerebral stroke) are diseases primarily of the elderly.

Many of the blinding diseases of the elderly have vision preserving or vision saving surgical interventions. The Assessing Care of Vulnerable Elders (ACOVE) report shows that 40% of blindness among the elderly is either preventable or treatable [6]. The recognition and treatment of eye disease in the elderly has benefits beyond their visual improvement. One such example is falls, a common and significant cause of increased morbidity and mortality in the elderly. There is clear evidence that visual loss increases the risk of falling in older patients [7–10]. The loss of contrast sensitivity, depth perception, visual field, or visual acuity all increase the risk of falls and fractures [7–10]. The Beaver Dam Eye Study, a large epidemiologic study, showed that 943 of 2365 (11%) of elderly patients with impaired vision experienced a fall in the previous year compared to 4.4% in controls [2].

Visual loss may complicate other systemic comorbidities such as hearing loss, depression [11, 12] and anxiety, dementia, or delirium in the elderly patients [13, 14]. Population studies have shown that visual impairment affects overall health and functioning [15–17], self-esteem, the ability to drive, independent functioning, and activities of daily living in the elderly [18–23].

Major Ophthalmic Conditions in the Elderly

Age-Related Cataract

A cataract is an opacity that occurs in the native, crystalline lens that increases in incidence and prevalence with age. The crystalline lens is located behind the iris. The lens is composed of lens epithelial fibers contained by an anterior and posterior capsule. It is suspended from the ciliary body by zonules, which attach around the equator of the lens for 360°. Cataracts scatter and defocus the incoming light and thus can produce symptoms of loss of acuity, loss of detail, loss of contrast sensitivity, and increased glare. The clear or cataractous lens may be viewed through the pupil with a direct ophthalmoscope, but the best tool is a slit lamp biomicroscope. Examination by an eye care professional can document the severity, type, and progression of cataract. The different types of cataract are classified by type and location within the lens (e.g., anterior or posterior, cortical, nuclear, or sub-capsular cataracts) (Fig. 42.1). The treatment for all visually significant and symptomatic cataracts is surgical extraction with placement of a synthetic or “pseudophakic” intraocular lens. The slit lamp appearance of the cataract and the quality

of the examiner’s view of the fundus through the cataract may both be used to estimate a patient’s likely visual potential after cataract surgery.

The American Academy of Ophthalmology (AAO) has developed written and specific guidelines in the form of a preferred practice pattern (PPP) for the evaluation, management, and surgical indications for cataracts. Although there are occasional exceptions, cataract surgery is considered an elective and outpatient procedure. In the elderly patient, the decision for cataract surgery is dependent upon the severity of the cataract, the functional status, the visual needs of the older patient, the individual patient’s preferences, and the likelihood of improved visual and overall function after surgery [5]. The presence of a cataract alone is therefore not a sufficient indication for surgery. The potential functional impact on the activities of daily living must be considered in the decision making. Chronologic age alone is not a sufficient reason to elect to perform or to deny a patient cataract surgery; patients in their 90s can undergo successful cataract extraction, and frequently elect to proceed with subsequent fellow eye surgery.

Modern cataract surgery requires that the patient lie in a supine to slight reverse Trendelenburg position for up to an hour, though the surgical time is frequently shorter. The patient’s face and torso are covered with a surgical drape with the surgical eye exposed. Anesthesia may be with topical agents, a retrobulbar injection, or general anesthesia based on patient factors such as anticoagulation, cooperation, and claustrophobia. Either a corneal or a scleral incision is used, with the surgeon viewing the field through an operating microscope. A continuous, circular opening or capsulorhexis is created in the anterior capsule, the lens removed, and the pseudophakic lens placed within the remaining anterior and posterior capsule. Phacoemulsification is currently the most common technique in the USA to remove the lens material. Ultrasound power is created by the vibration of a piezoelectric crystal located within the phacoemulsification handpiece, and is used to emulsify the lens. The lens fragments are aspirated from the eye through the same handpiece. Modern cataract surgery techniques are, in general, both well tolerated and efficient, and in the vast majority of cases produce an improvement in both visual and functional outcome with limited morbidity and mortality. Numerous studies have demonstrated the subjective and objective visual and functional benefit for cataract extraction in the overwhelming majority of patients (up to 92%) [24]. Local, and increasingly topical anesthesia techniques, allow for rapid surgical and recovery times, while minimizing the risk to the patient. The procedure itself has very low peri-operative and post-operative morbidity (e.g., bleeding, infection, increased intraocular pressure, retinal detachment, macular edema, need to remove intraocular lens) and exceedingly rare mortality. One relatively common post-operative event is posterior capsular opacification

FIGURE 42.1 Cataracts. (a) Nuclear cataract. (b) Cortical cataract. (c) Posterior subcapsular cataract. (d) Posterior capsular opacity after YAG laser capsulotomy (photos courtesy of The University of Iowa Department of Ophthalmology and Visual Sciences).

that may occur months to years after surgery. The capsule which surrounds the native lens preoperatively and now holds the replacement intraocular lens postoperatively may develop a secondary opacity (i.e., a posterior capsular opacification). This opacity may be treated using laser energy to produce a central opening in the capsule to clear the visual axis (i.e., YAG laser capsulotomy).

Age-Related Macular Degeneration

ARMD occurs most frequently in patients older than 50 years of age and increases in incidence and prevalence with increasing age. ARMD is a degenerative condition of the central portion of the retina called the macula, which is located temporal to the optic nerve and wrenched by the retinal vascular arcades. The receptive cells of the retina, the retinal photoreceptors, are supported by an underlying layer of retinal pigment epithelium (RPE). The RPE is in turn supplied by the underlying choroidal blood vessels. ARMD involves age-related damage to the photoreceptor and pigment epithelial layers of the retina.

ARMD is often classified into the “dry or wet” forms. The more common “dry form” presents with a loss of RPE, which may progress to geographic atrophy of the RPE within the macula, and may be associated with the formation of drusen. There is a secondary loss of the overlying photoreceptors and a resultant decrease in acuity. Patients with the “dry form” of ARMD may be asymptomatic (e.g., macular drusen) or may complain of unilateral or bilateral central visual loss. The visual loss may be static or slowly progressive and there is currently no effective treatment for the “dry form” of ARMD. Dry ARMD can be divided into three stages: (1) Early dry ARMD (i.e., small drusen or a few medium-sized drusen); (2) Intermediate dry ARMD (e.g., many medium-sized drusen or one or more large drusen); and (3) Advanced Dry ARMD with drusen and geographic atrophy of the RPE. The less common, but more visually disabling “wet form” of macular degeneration involves ingrowth of blood vessels from the choroid to the subretinal space (subretinal neovascularization) which leak serous fluid or hemorrhage. Patients present with distortion of their vision or sudden vision loss. Although age is the greatest risk factor for both forms of ARMD, other risk factors for ARMD include smoking,

FIGURE 42.2 Age-related macular degeneration. (a) Dry form of ARMD characterized by drusen. (b) Wet form of ARMD with subretinal edema and exudate produced from an underlying choroidal neovascular membrane.

family history, blue eyes, obesity, white race, and female gender. The disease ophthalmoscopically is characterized by the following typical findings (Fig. 42.2) [25–30]:

1. Macular drusen (i.e., deposits of lipofuscin) under the retina forming visible yellow spots on ophthalmoscopic exam.
2. RPE hypopigmentation or hyperpigmentation.
3. Geographic atrophy of the RPE and underlying choriocapillaris.
4. Exudative neovascular maculopathy (i.e., the “wet form” of ARMD) with choroidal neovascularization, serous/hemorrhagic detachments of the sensory retina or RPE; hard exudates or hemorrhages, and subretinal or sub-RPE fibrovascular proliferation and eventually a disciform scar.

There remains no cure for ARMD, but newer preventive and therapeutic measures are being developed and tested [25–30]. Although a full description of the preventive dietary and lifestyle changes in ARMD is beyond the scope of this chapter, several studies have shown benefit in specific forms of ARMD. In the Age-Related Eye Disease Study (AREDS), a combination of antioxidants plus zinc (Table 42.1) was recommended for those patients with ARMD who are at high risk for developing advanced ARMD. These high risk individuals in this study were defined as those having (1) intermediate ARMD changes in one or both eyes characterized by the presence of either many medium-sized drusen or one or more large drusen or (2) advanced ARMD in one eye only characterized as either a breakdown of the light-sensitive cells and supporting tissue (RPE) in the macula (i.e., the advanced “dry form” of ARMD), or the development of the abnormal and fragile, leaky, new blood vessels under the retina (i.e., the “wet form” of ARMD). An eye care professional should examine the patient prior to instituting therapy as patients with early ARMD did not have benefit from treatment in the AREDS.

TABLE 42.1 AREDS multivitamin plus zinc formula [31]

500 mg of vitamin C
400 IU of vitamin E
15 mg of beta-carotene (often labeled as equivalent to 25,000 IU of vitamin A)
80 mg of zinc as zinc oxide
2 mg of copper as cupric oxide

The use of the AREDS supplements and other alternative and complementary therapies should be discussed with the patient and coordinated with their primary care provider. There are theoretic and real risks of side effects and drug interactions for all medications including vitamin and nutritional supplementation. The higher zinc concentration in the AREDS supplements can produce copper deficiency anemia, and copper was therefore included in the AREDS formulation. In addition, in the “antioxidants plus zinc” or “zinc alone” treatment arms there were genitourinary side effects, some of which required hospitalization (e.g., urinary tract infections, kidney stones, incontinence, and enlarged prostate) [31]. There is a risk of lung cancer in patients who smoke and who also take vitamin A. A “smoker’s formula” of the AREDS multivitamins lacking the beta-carotene and substituting lutein is now commercially available; this formula was not available during the AREDS trial, and has not been clinically tested or found equivalent to the original AREDS formula.

As opposed to the “dry form” of ARMD, the “wet form” of ARMD is characterized by hemorrhage or exudate from new blood vessel formation under the retina (i.e., choroidal neovascular membrane). The wet form is considered advanced ARMD and therapy with the AREDS multivitamins should be instituted. Patients with subretinal neovascular membranes may be asymptomatic if the lesion is extrafoveal, or may be symptomatic with central or

paracentral visual loss or visual distortion with subfoveal or juxtafoveal involvement. These patients often describe distortion of straight lines (i.e., metamorphopsia), or may have changes in image size (e.g., micropsia, macropsia) in addition to the loss of central acuity and a central scotoma (“blind spot”) on visual field testing. The exudative “wet” form of ARMD in the past could sometimes be treated with laser therapy to eliminate the underlying subretinal neovascularization, but these membranes often recurred. Although the laser treatment destroys the fragile, leaky subretinal neovascularization, the laser is also destructive to the surrounding healthy retinal tissue and produced acute worsening of vision in centrally located (subfoveal) lesions. Only a small percentage of people with wet AMD can be successfully treated with laser because of the limitations based on total treatment size and on SRNVM characteristics. The laser is more effective for neovascularization that is adjacent to the fovea (juxtafoveal) rather than under the fovea (i.e., subfoveal). Recurrent membranes and the formation of new membranes are common in all locations, and repeated treatments are frequently necessary.

A subsequent adjunct to laser therapy is the use of a photosensitizing drug called verteporfin [32]. The laser light activates the drug within the membrane and enhances the laser’s destructive effect on the fragile blood vessels of the SRNVM, allowing lower laser power use and producing less damage to the surrounding retina.

Modern therapy for “wet” ARMD has rapidly progressed and is now based on identified vascular endothelial growth factors (e.g., VEGF) that promote subretinal neovascularization. Anti-VEGF agents are now injected directly into the vitreous cavity, allowing for rapid regression of the neovascular membrane and stabilization or even return of vision. A series of multiple injections are frequently necessary. It is beyond the scope of this chapter to discuss the details of these agents, but early recognition and referral of treatable cases of ARMD is essential in both in the “dry” and “wet” forms [25–30]. We recommend that all patients with known ARMD be given information on the symptoms of ARMD progression (e.g., metamorphopsia) and a take home testing grid (i.e., Amsler grid), as well as regular monitoring by an eye care professional.

Glaucoma

Glaucoma is a common cause of visual loss in the elderly, affecting up to 2.5% of the population over the age of 40 years with an increasing incidence and prevalence with increasing age. Race influences the risk of developing glaucoma; glaucoma is present in up to 10% of elderly African Americans as compared with 2% of white patients. The etiology and

pathogenesis of glaucoma remain debated and are likely multifactorial. The disease is characterized pathologically by the loss of retinal ganglion cells beginning with those that pass through the superior and inferior poles of the optic nerve. The progressive loss of nerve fibers leads to a specific appearance of atrophy of the optic nerve, visible ophthalmoscopically as “cupping” of the optic disc (Fig. 42.3). The superior and inferior loss present with vertical elongation of the cup or even notching of the rim. The classification and description of the multiple types of glaucoma is beyond the scope of this text, but in general glaucoma is classified based upon the appearance of the draining apparatus (anterior angle) of the eye. The angle may be open (e.g., open angle glaucoma) or closed (i.e., angle closure glaucoma). Both forms of glaucoma may be primary or secondary (e.g., due to inflammation, trauma, neovascularization, mass effect, etc.). Primary open angle glaucoma (POAG) is the most common form in the elderly and will be the focus of the remainder of our discussion.

POAG is generally an adult disease with a bilateral, but often asymmetric presentation. The disease may initially be asymptomatic and is slowly progressive [33, 34]. Although increased intraocular pressure (IOP) above 21 mmHg is a risk factor for glaucoma, it is not the only factor, and some patients develop glaucomatous optic atrophy with “normal” pressures (i.e., normal tension glaucoma). Conversely, some patients with chronically elevated intraocular pressures may never develop glaucoma (ocular hypertension). The optic nerve damage of glaucoma produces painless, gradual, progressive visual field loss in a characteristic pattern. The peripheral

FIGURE 42.3 Glaucoma. (a) Glaucomatous cupping of the optic nerve OD.

visual field is affected first, with the scotoma on formal visual field testing classically presenting in an arcuate pattern that is consistent with damage to the superior or inferior retinal nerve fiber layers. The appearance of atrophy of the optic nerve should match that expected based on the visual field. As opposed to ARMD where central visual loss is often the presenting symptom, the visual acuity and central vision tend to be preserved until late in the course of glaucoma.

Unfortunately, there is no cure for POAG. Medical treatments to lower the IOP with topical or less commonly systemic agents are the first line of therapy, and are used even in patients with borderline or normal IOP, but who have glaucomatous visual loss. The AAO has a PPP for POAG. In this PPP, the AAO recommended a 20% target reduction in IOP in POAG with progressive visual field loss and glaucomatous optic nerve damage. The management of POAG in the elderly is similar to that in younger patients, but there are some special considerations. Topical beta blockers, the previous “gold standard” of topical therapy, may not be the best first line choice in older patients with orthostatic hypotension as the beta blockade can cause or exacerbate hypotension, mask hypoglycemia in the diabetic, and exacerbate chronic obstructive pulmonary disease (COPD). Patients with severe degenerative arthritis may have difficulty administering their topical medications and might require assistance or special accommodations in this regard.

As stated above, glaucoma can occur despite normal IOP. In the Collaborative Normal Tension Glaucoma Study Group (a multicenter, randomized, and controlled trial), the treatment with IOP lowering agents produced a 20% reduction in rate of visual field loss at 3 years and a 40% reduction at 5 years if the IOP was reduced by 30% compared to untreated eyes [35, 36]. As with all treatment decisions, the AAO PPP recommends that the choice of treatment take into consideration the patient’s quality of life, physical, visual, medical, psychological, and social circumstances [33].

POAG patients who have progression despite maximum tolerable medical therapy may require surgical treatment with either laser or incisional glaucoma surgery. As with medical treatment, the goal of laser or surgical therapy to lower the IOP to an acceptable target level is to prevent further loss of vision. With laser trabeculoplasty, the laser is applied to the trabecular meshwork in the angle of the eye to improve the outflow of aqueous fluid from the eye and lower IOP. Various types of incisional glaucoma surgery can also be performed (e.g., filtering surgery, tube shunts) to augment or bypass the eye’s normal outflow system in the angle and lower IOP to a target level.

Diabetic Retinopathy

Diabetes occurs with increasing incidence with age, thus diabetic retinopathy is a common cause of visual loss in the

elderly [37–41]. Both type I and type II diabetes may produce diabetic retinopathy, and because the incidence and severity of diabetic retinopathy increases with the duration of systemic disease, older patients are in general at higher risk for visual complications from diabetes. There are two types of diabetic retinopathy. The first type involves small vessel damage with hemorrhage and leakage, but is not associated with new blood vessel formation (i.e., non-proliferative diabetic retinopathy), and may or may not progress in an individual patient to new blood vessel formation (i.e., proliferative diabetic retinopathy). The non-proliferative form presents with retinal vascular changes, hemorrhages, and exudates (Fig. 42.4). Leakage of fluid from retinal microaneurysms into the central macula can produce retinal edema and visual loss (i.e., diabetic macular edema). Nonproliferative diabetic retinopathy without macular edema is usually asymptomatic, however. The type II diabetic is more likely to manifest diabetic macular edema, although it can occur in either form of diabetes. In contrast, proliferative diabetic retinopathy presents with new blood vessel formation (i.e., diabetic neovascularization) induced by vascular growth factors produced by the ischemic retina. These new blood vessels are often seen as net-like, friable fronds that can produce intraocular bleeding (i.e., vitreous hemorrhage) and secondary visual loss. Subsequent neovascular growth vertically into the vitreous scaffold or tangentially along the retina may produce a tractional retinal detachment. As the disease progresses, neovascularization may also develop on the iris or within the anterior chamber angle, leading to often intractable secondary neovascular glaucoma.

There is no medical cure for diabetic retinopathy. Tight control of blood glucose is recommended as the first line for the prevention and treatment of diabetic retinopathy. The Diabetes Control and Complications Trial (DCCT), is a randomized trial of patients with type I diabetes mellitus who were assigned either to intensive or to conventional glucose control. The aim of the intensive treatment arm was to achieve normal or near-normal blood glucose levels and target optimal glycosylated hemoglobin (hemoglobin A1c) levels. Four years after randomization, the proportion of diabetic patients with worsening diabetic retinopathy (e.g., proliferative retinopathy, macular edema, and the need for laser therapy) was lower in the intensive-therapy group compared with controls (odds reduction 72–87%, $P < 0.001$) [37]. Finally, hypertension and hyperlipidemia, often associated with diabetes, can both worsen diabetic retinopathy and should be optimally treated in patients with diabetic retinopathy.

Although there is no cure for diabetic retinopathy, that which reaches specific guidelines may be treated with laser therapy. Proliferative diabetic retinopathy may be treated with laser throughout the peripheral retina (i.e., panretinal photocoagulation) to destroy the ischemic retina and reduce the angiogenic stimulus for diabetic neovascularization. In contrast, patients with macular edema are treated with

FIGURE 42.4 Diabetic retinopathy. (a) Non-proliferative diabetic retinopathy characterized by dot and blot retinal hemorrhages and macular edema with exudation. (b) Proliferative diabetic retinopathy

characterized by neovascularization (new blood vessels) and retinal traction (courtesy of Thomas A. Weingeist, MD). (c) Periperal laser photocoagulation therapy for proliferative diabetic retinopathy.

focal laser treatments applied directly to the leaking microaneurysms or in a grid pattern to diffusely leaking macular tissue to reduce diabetic macular edema and improve the visual function. Multiple prior studies have demonstrated that laser treatment reduces the incidence and severity of visual loss and blindness due both to proliferative diabetic retinopathy and macular edema, and panretinal photocoagulation for proliferative diabetic retinopathy significantly reduced blindness [38–41]. Patients with diabetic tractional retinal detachments or non-resolving vitreous hemorrhages may also benefit from vitreoretinal surgery (e.g., vitrectomy with membrane peel).

Giant Cell Arteritis

Giant cell arteritis (GCA), also known as temporal arteritis, is a systemic inflammatory vasculitis affecting medium to large-sized arteries [42]. GCA is a disease of the elderly, especially older women. The dreaded complication of untreated GCA is permanent visual loss, typically

due to arteritic anterior ischemic optic neuropathy. GCA is associated with systemic symptoms including new onset headache, scalp tenderness, ear or neck pain, pain with chewing (i.e., jaw claudication), and temporal artery pain or tenderness. The visual loss in GCA is often severe, and can be bilateral and simultaneous, or sequential. Although the visual loss is generally due to ischemia of the optic nerve (i.e., ischemic optic neuropathy), non-embolic central retinal artery, cilioretinal artery, or ophthalmic artery occlusions, as well as choroidal ischemia can occur (Fig. 42.5). Ischemic optic neuropathy typically occurs in the setting of swelling of the anterior portion of the optic disc that is visible within the eye (i.e., anterior ischemic optic neuropathy or AION), but in GCA the disc may appear normal (i.e., posterior ischemic optic neuropathy or PION) despite visual loss and evidenced by an optic neuropathy. Specialized testing (e.g., fluorescein angiography) may show choroidal perfusion delay in patients with GCA and visual loss due to AION or PION.

A staterythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP) should be performed in patients suspected of having GCA, but normal laboratory testing does not exclude

FIGURE 42.5 (a) Swollen optic nerve with disc hemorrhage in anterior ischemic optic neuropathy from giant cell arteritis. (b) Fluorescein angiogram demonstrating choroidal perfusion delay in choroidal

distribution consistent with giant cell arteritis [(b), courtesy of The University of Iowa Department of Ophthalmology and Visual Sciences].

GCA. Most patients with GCA have an elevated ESR (typically >50 mm/h), and the combination of the ESR and a CRP increases the sensitivity and specificity of either test alone.

In general, unless there are strong contraindications to treatment, patients suspected of having GCA should begin immediate corticosteroid therapy (e.g., oral prednisone at 1–1.5 mg/kg/day) and be scheduled for a confirmatory temporal artery biopsy with the next few weeks. It is highly recommended to confirm the diagnosis of GCA by temporal artery biopsy as the incidence of steroid related complications during treatment is high. When faced with steroid complications, a history of a positive biopsy reinforces the need to continue steroid or steroid sparing therapy for a full course of treatment. Although a unilateral temporal artery biopsy has a sensitivity of about 95% for the detection of GCA, if the clinical suspicion for the diagnosis remains high in the setting of a negative biopsy, then a contralateral biopsy should be considered [42]. Skip lesions, inadequate sample size, or inaccurate pathologic interpretation can produce false negative results in unilateral or even bilateral temporal artery biopsies.

Non-arteritic Anterior Ischemic Optic Neuropathy

In contrast to arteritic anterior ischemic optic neuropathy, patients can have ischemic optic neuropathy without GCA. The non-arteritic form of anterior ischemic optic neuropathy (NAION) is more common than the arteritic form, but the diagnosis of GCA should be considered in these patients. Like the arteritic form, NAION is characterized by acute unilateral visual loss, an ipsilateral relative afferent pupillary defect (RAPD), and a swollen optic nerve. NAION is typically associated with vasculopathic risk factors (e.g., hypertension, diabetes, smoking, and elevated cholesterol), but the precise etiology for NAION remains elusive. The major clinical consideration in AION in the elderly patient is excluding GCA (e.g., ESR/CRP and temporal artery biopsy). There is no proven effective treatment for NAION and management is typically directed against modifying the treatable vasculopathic risk factors and reducing the fellow eye risk for NAION.

CASE STUDY: RESOLUTION

We now return to our 87-year-old patient who presents with blurred vision in both eyes. The patient is brought in by her family for second opinion of progressive vision loss with declining activities of daily living and recent falls. This time the appropriate history and examination confirm that she had treatable cataracts, and reveal that part of her poor compliance with her glaucoma and dia-

betic regimens is because of her vision. Although she has a long standing history of poorly controlled diabetes mellitus, she now discloses that she is unable to check her blood glucose and administer her medications. She undergoes uncomplicated, sequential cataract extraction with intraocular lens placement under topical anesthesia. After the cataract extraction, her compliance with monitoring and treating her blood glucose improves. Her dizziness improves after her topical ocular anti-hypertensive therapy

(continued)

CASE STUDY (continued)

is switched from a beta blocker to a prostaglandin inhibitor. Her intraocular pressure measurements improve to normal and she proudly reports regular compliance. She has a 50 pack year tobacco history, but after realizing the improvement of her vision and reviewing the impact of tobacco on both glaucoma and macular degeneration she commences with smoking cessation treatment through her primary physician. The patient's diabetic retinopathy remained stable. Her vision improves to 20/20 in both eyes. She returns to driving and has not had a falling

episode since her last surgery. Although the cup to disc ratio remains 0.8 OU, she is better able to complete her formal visual field testing, which shows bilateral, but stable paracentral arcuate visual field loss. The drusen and geographic atrophy of the RPE are consistent with the dry form of severe age-related macular degeneration. She is started on AREDS formulation supplement therapy. Her family members feel that her mood and affect are improved after cataract surgery, and thank her new ophthalmologist for "not giving up on her" just because she is older.

TABLE 42.2 Visual loss in the elderly

Etiologies: Cataract, age-related macular degeneration (ARMD), glaucoma, diabetic retinopathy, ischemic optic neuropathy, giant cell arteritis
Worsens: Depression, dementia, fall risk and fractures, and hearing loss
Affects independence and daily activities
Prevention, therapy, and improvement with minimally invasive treatment

Summary

Non-ophthalmic care providers should be aware of the major age-related causes of visual loss in the elderly (e.g., cataract, ARMD, glaucoma, diabetic retinopathy, ischemic optic neuropathy, giant cell arteritis), should recognize the key features of each disorder, and should refer in a timely and appropriate manner to ophthalmology for evaluation and treatment. Visual loss has secondary impact on the elderly patient, including worsening of co-morbidities such as depression, dementia, fall risk, and hearing loss. Treating the visual loss might decrease the functional impact of these comorbidities (Table 42.2).

Chapter 43

Anatomic and Physiologic Changes in the Ears, Nose, and Throat

Ara A. Chalian and Sarah H. Kagan

Physiologic changes with age

Parameter	Change with age	Functional impact of change
<i>The Ear</i>		
Cartilage	Structural collapse	Potential cerumen impaction
Skin	Increased hair growth	Pruritus
	Increased cerumen	Potential cerumen impaction Limited hearing aide use
Ossicles	Increased rigidity	No known impact
Cochlea	Atrophy	Composite hearing loss
		Hair cell loss
Organ of corti	Vascular changes	Neural fiber degeneration
Stria vascularis		Decreased synapses
Auditory nerve	Decreased neurons	Hearing loss
	Decreased neuron size	
Central processing	Atherosclerosis	Hearing loss out of proportion with audiogram
Utricle and saccule	Decreased hair cells	Altered otoconia membrane
	Altered vestibular reflexes	
	Otoconial debris	Vertigo Falls/unsteadiness
<i>The Nose</i>		
Olfactory epithelium	Decreased neurogenesis	Composite change in olfaction
	Increased respiratory epithelium	Decreased olfactory sensation
		Danger – detecting noxious odors
		Altered nutrition Quality of life
	Decreased olfactory receptor neurons	
	Decreased olfactory cilia	
	Atrophy	Rhinitis
<i>The Throat</i>		
Laryngeal skeleton	Decreased elasticity	Contribution to voice changes
	Increased rigidity	Pitch Smoothness Projection
Mucosa/lamina propria	Increased vocal fold density	Vocal instability Rough phonation

Introduction

Physiological and anatomical changes with age in the ear, nose, and throat have long been the subject of clinical interest; increasingly, they are the subject of basic and clinical investigations [1–7]. Nonetheless, the role of alterations in

A.A. Chalian (✉)
Department of Otorhinolaryngology: Head and Neck Surgery,
Hospital of the University of Pennsylvania, 3400 Spruce Street,

e-mail: chaliana@uphs.upenn.edu

cells and tissues and distinctions among genetic, pathological, environmental, and interactive effects on cellular, tissue, and organ function are still emerging [3, 8–13]. Currently, presbycusis, presbystasis, presbyosmia, presbylarynx, and presbyphonia are the terms used to denote the functionally and clinically apparent manifestations of aging changes in the ear, nose, and throat [1, 2, 7, 14–18]. Presbyvertigo has also been proposed as a relevant term for matters of dizziness and falls in older adults though presbystasis is more commonly used [18]. Notably, presbypharynx is, while a parallel term to represent the manifestations of aging changes in the anatomy and physiology of the pharynx, not used in current literature. Instead, various uses of senescent swallowing and dysphagia predominate in the literature [19].

Research into conditions of the aging ears, nose, and throat offers a disparate and inconsistent body of evidence that connects aspects of the biology of aging, anatomy and histology, and functional changes. Related clinical literature has developed differentially, often relying on clinical observation and correlative science as well as treatment experience and case series reports. The magnitude of applicable science specific to the ears, nose, and throat varies by organ and senescent function. Similarly, the quality and quantity of translational science is inconsistent. Presbycusis is, for example, well studied with science that illuminates functional effects and clinical pearls [1, 20]. Conversely, presbyphonia and presbylarynx are only recently receiving significant attention in basic and clinical science [21]. Even with growing evidence of mechanisms, processes, and effects, direct translation of this evidence to care of the older surgical patient remains limited. Application thus requires careful review and interpretation.

This chapter describes important known anatomical and physiological changes with aging in the ear, nose, and throat. Each organ is addressed separately with focus on relevant changes in organ anatomy and physiology, and the chapter highlights alterations in function that result in presbycusis, presbystasis, presbyosmia, presbylarynx and presbyphonia, and senescent oropharyngeal anatomy and physiology, respectively. The sections detailing functional conditions of aging conclude with a brief summary of clinical surgical considerations. The chapter concludes with a summary of highlights.

The Aging Ear

Auditory Anatomy and Physiology

Targeted review of the anatomy and physiology of the ear predicates understanding presbycusis and presbystasis and their impact on function and implications for surgical care [1, 2, 7]. This section reviews in sequence the anatomy of the

ear and aspects of physiology relevant to understanding presbycusis and presbystasis.

External Ear

The external ear, from pinna through ear canal to tympanic membrane, captures and intensifies sound in the 2–5 KHz range – frequencies in much of human speech – by acting as a resonator [15, 16, 22] (see Fig. 43.1). These external structures change with advancing age. Importantly, cartilage collapses, resulting in somewhat deceptive appearance of larger ears for many elders. Further, the tympanic membrane and the ossicular chain in the middle ear stiffen, though the functional impact is minor. The conductive aspects of hearing promoted by these structures do not change appreciably with age [9] (see Fig. 43.2). Instead, concerns that are cosmetic and mildly distressing emerge, including larger

FIGURE 43.1 The ear and its divisions (reprinted from Lalwani AK. *Current diagnosis and treatment of otolaryngology, head and neck surgery*, 2nd edn, with permission from McGraw Hill Companies).

FIGURE 43.2 The ear (reprinted from Waxman SG. *Clinical neuroanatomy*, 26th edn, with permission from McGraw Hill Companies).

FIGURE 43.3 The middle ear (reprinted from Lalwani AK. *Current diagnosis and treatment of otolaryngology, head and neck surgery*, 2nd edn, with permission from McGraw Hill Companies).

pinna size, more apparent cerumen production, and growth of excessive hair in the pinna. Cerumen and hair growth often result in complaints of pruritus. While these matters may seem minor, they may influence acceptance and use of hearing aides as well as prove distressing to some older adults as they consider changes in appearance.

Middle Ear

Sound perception begins with vibration of the ossicular chain [23, 24] (see Figs. 43.2 and 43.3). The tympanic membrane and the ossicles (viz. malleus, incus, and stapes) are fairly resistant to aging changes unlike larger skeletal bones. Thus, age-related considerations and functional impact here are minor if they are present at all [23].

Cochlea

The cochlea is the anterior portion of the inner ear, called the bony labyrinth, which also contains the vestibule and the semicircular canals [15] (see Fig. 43.4). This hollow bone contains the neuroepithelium for auditory perception (cochlea) and balance perception (vestibule and semicircular canals) [16]. This section addresses aging changes in the cochlea and the resultant condition of presbycusis. Alterations in the vestibule and semicircular canals are discussed in a following section to explicate presbystasis as a separate condition of aging in the ear.

A membranous canal, known as the cochlear duct, wraps around a central bony core, the modiolus, for two and a half to two and three-quarters turns through which the auditory nerve fibers penetrate [9] (see Figs. 43.5 and 43.6). The cochlear duct is divided into three compartments: the scala tympani, scala media, and scala vestibule (see Fig. 43.7). The scala media has a fluid composition (endolymph) different from that of the other two compartments (perilymph) and contains the organ of Corti, which is the sensory organ of hearing [9] (see Fig. 43.5). The organ of Corti rests on the basilar membrane, which separates the scala media from the scala tympani (see Fig. 43.6). The organ of Corti contains afferent nerve endings (about 3,500 inner hair cells), afferent/efferent nerve endings (approximately 12,000 outer hair cells), and a variety of other supporting cells. The hair cells communicate with the dendritic terminals of the bipolar cochlear neurons whose cell bodies are located within the modiolus. The hair cells serve as mechanoreceptors, converting the mechanical energy of basilar membrane displacement into an action potential to stimulate the ganglion cells. The cochlea's capacity to analyze periodicity, synchrony rate, phase, and spread of excitation of sound results in specific ganglion cell population stimulation and ultimately the perception of sound frequency patterns in the auditory cortex. The normal function of the cochlea occurs as sound energy in the form of vibrations reaches the oval window, the basilar membrane is set into motion and vibrates. The stereocilia of the hair cells on the basement membrane move and increase the permeability of the hair cell to potassium that depolarizes the hair cell (see Fig. 43.8).

FIGURE 43.7 The cochlea, cross sectional view (reprinted from Lalwani AK. Current diagnosis and treatment of otolaryngology, head and neck surgery, with permission from McGraw Hill Companies).

A neurotransmitter is released by the hair cell onto the afferent ending of the cochlear nerve leading to a neurological signal [23].

Cochlear changes with advancing age result in presbycusis [15, 25]. Among the most significant alterations in anatomy and physiology include atrophy in the organ of Corti, vascular changes that affect the stria vascularis, and collapse of the cochlear duct [9, 26, 27]. These changes lead to hair cell loss, neural fiber degeneration, and reduction in number of synapses at the base of the hair cells [9, 25]. Accumulation of cochlear debris in the spiral bundles, abnormalities of the dendritic fibers and their sheaths in the osseous spiral lamina, and degenerative changes in the spiral ganglion cells and axons follow.

Auditory Nerve

The auditory nerve consists of about 30,000 afferent and 1,000 efferent bipolar neurons [9]. Ninety-five percent of the spiral ganglion is composed of myelinated (type 1) fibers that innervate only inner hair cells and nonmyelinated (type 2) fibers that innervate outer hair cells. The spiral ganglion is the densest at the mid and basal portions of the modiolus. The nerve fibers course in the nerve trunk in an orderly spatial arrangement (basal fibers located at the periphery and inferior portion of the nerve) through the temporal bone into the cerebellopontine angle into the pons to enter the cochlear nuclei [22].

Central Auditory Processing

Central auditory processing involves the cochlear nerve, the cochlear nuclei, and the auditory cerebral cortical regions [9, 28]. Through this process, the neuronal signal is appreciated as sound and interpreted by the cognitive regions of the brain to recognize content [16]. The process is bilateral. Three morphologically distinct auditory nuclei are appreciated within the pons. Upon entering the pons each fiber divides into an anterior branch, which terminates in the anterior part of the ventral cochlear nucleus, and a posterior branch, which again divides to terminate in the posterior part of the ventral cochlear nucleus and the dorsal cochlear nucleus.

FIGURE 43.8 A hair cell (reprinted from Waxman SG. Clinical neuroanatomy, 26th edn, with permission from McGraw Hill Companies).

Cells from these nuclei send axons in a complex pattern from the contralateral superior and accessory olive areas to the lateral lemniscus, the inferior colliculus, and through the medial geniculate body to the auditory cortex in the temporal lobe [22].

Aging results in decrease in neurons in the cochlear nuclei and auditory centers [16]. Neurons decrease in size as well, thus altering their physiology. Diseases and injuries that alter brain anatomy and physiology – such as cerebral atherosclerosis and stroke or mild cognitive impairment and dementia – may further alter central auditory processing [16]. Changes in central auditory processing account for complaints in hearing that exceed that anticipated by the audiogram [29]. These changes are manifest in limited auditory comprehension in noisy environments and in failure of simple amplification through hearing aides to remedy complaints of dysfunction [29]. The effects of normal brain

aging on central auditory processing are a focus of dedicated current investigation [20, 30, 31].

Auditory Function

Changes in auditory function resulting in hearing impairment associated with aging is termed presbycusis, a prevalent and disabling condition [15]. Presbycusis results largely from aging changes in the inner ear and is a form of sensorineural hearing loss. Subtypes, however, can be detected on audiogram though the differences are likely to be functionally undetectable. They are sensory, neural, strial, and cochlear conductive presbycusis [15, 16]. Conductive hearing loss per se does not play a role in presbycusis. Early presbycusis effects high-frequency range, beyond the frequency characteristics of the human voice [15, 16]. Thus, early alterations in function are often imperceptible to older adults. With advancing age, hearing loss encroaches on the speech frequencies. Impairment then becomes consequential in daily activities. Despite the expectation of presbycusis, hearing loss among older adults is often multifactorial. The contribution of central auditory processing changes, along with the influence of genetics and family history of congenital hearing loss, cumulative environmental damage through occupational or leisure exposure, and use of ototoxic drugs should be considered [9, 10, 22]. Aminoglycosides and some chemotherapeutic agents are commonly identified as ototoxic medications. Additionally, other drug classes such as loop diuretics and beta blockers may damage auditory function, albeit in a manner that may be reversible [22].

Clinical Implications

Presbycusis, while seemingly peripherally related to surgical care, has direct impact on all processes of care from decision making through perioperative care to self-care after surgery. Gates and colleagues [32] suggest the simple screening question “Do you have a hearing problem now?” as the means to assess for impairment that results in disabling limitations in function. In elective surgeries, opportunity to refer for otolaryngologic assessment and clinical audiometric testing should result in improved interdisciplinary care. Emergent surgical care, conversely, requires anticipation of problems that require compensation including decision making, patient and family education, and postoperative care and the risk of reactions to the environment of care. Importantly, those older adults who wear hearing aides require additional support as their presbycusis may be inadequately corrected and central auditory processing problems unaddressed.

FIGURE 43.9 The vestibulo–ocular reflex (reprinted from Lalwani AK. Current diagnosis and treatment of otolaryngology, head and neck surgery, with permission from McGraw Hill Companies).

Vestibular Anatomy and Physiology

The vestibule is composed of three semicircular canals, the portions of the inner ear that are responsible for balance (see Fig. 43.5). The canals are posterior, superior, and horizontal, accounting for the dimensions in which the body is positioned in the physical environment of space [9, 10]. The otolithic organs are the utricle and the saccule; they are structured to respond to linear acceleration of the body in space [9, 10, 22]. The macula is the sensory portion of the utricle and the saccule. Type II hair cells are those that function in the vestibule (see Fig. 43.8). These cells are cylindrical with efferent and afferent synapses. Each type II hair cell contains approximately 50–100 stereocilia and one kinocilium. The kinocilium is located on one end of the hair cell, imparting anatomical polarization. Movement of the hair bundle toward the kinocilium causes an increase in the firing rate of the hair cell, while deflection away causes a decrease in the firing rate. In the lateral semicircular canal, the kinocilium is located near the utricle [9, 27]. The opposite is true in the superior and posterior semicircular canals (see Fig. 43.5). Cilia extend from hair cells to touch the statoconial membrane. It has a gelatinous consistency with calcareous particles embedded in that gelatinous layer. The surrounding endolymph has a lower specific gravity and, hence when the body accelerates, the hair cells of the macula are triggered. The central section of the statoconial membrane is called the striola. In the utricle, the hair cells are toward the striola. In the saccule, they are oriented away from the striola, again accounting for spatial dimension and direction of movement. The bipolar vestibular neurons create the inferior and superior vestibular neurons that merge when entering the brainstem [9, 27]. The vestibule is supplied by the labyrinthine artery.

The vestibular system senses linear and angular acceleration of the body. The semicircular canals sense angular acceleration while the otoliths sense linear acceleration. This system also coordinates eye–head movement. The vestibulo–ocular reflex enables focus on an object (see Fig. 43.9). The vestibule–spinal reflex accounts for postural placement of the body. Together, these physiological functions contribute to a sense of the body in space [33, 34]. Together with visual sensation and peripheral nervous system sensation in the feet, the vestibular reflexes create the complex sensory-perceptual system of proprioception [34]. Vestibular changes with age include alterations in the otoconia and in the hair cells [12, 18, 35, 36]. Atherosclerosis in the vascular supply and decline in the number of neurons in the vestibule further contribute to dysfunction and to altered vestibulo–ocular and vestibulo–spinal reflexes. Nevertheless, direct observation of the actual dysfunction is not possible given current assessment technology. Thus, clinical assessment relies on diagnosis by exclusion, employing means of inference including the caloric reflex test and other forms of electronystagmography [13, 18, 34]. These tests attribute vestibular function through manipulation of the vestibulo–ocular and the vestibulo–spinal reflexes and may create acute discomfort for patients [34].

Vestibular Function

Presbystasis is the condition in which age-related changes in the vestibular system result in altered balance and symptoms of dizziness and vertigo [2, 7, 18]. Vertigo and dizziness are common presenting complaints among older adults [10, 13, 37–39]. Nonetheless, presbystasis is a diagnosis of

exclusion as vision and peripheral proprioception contribute to the sensation of dizziness and vertigo, which may culminate in a fall. Agrawal and colleagues [13] provide an elegant analysis of the prevalence of vestibular dysfunction among adults using a four-step test. The fourth step relies on standing on a foam-covered surface with an eye shield in place to isolate vestibular function. In their sample drawn of over 6,700 adults in the National Health and Nutrition Examination Survey, more than a third showed signs of vestibular dysfunction and could not remain standing without visual and proprioceptive cues. Prevalence was significantly associated with age. Almost half of those aged 60–69 and more than two-thirds of those aged 70–79, while the great majority of those over 80 years showed vestibular dysfunction [13]. Thus, the functional state of dizziness is likely to be presbystasis among the very old. However, aligned conditions such as benign paroxysmal positional vertigo (BPPV) and Meniere's disease must not be excluded [10, 37, 38]. BPPV is, in particular, a competing diagnosis that may create great distress from the periodic nature of its presentation. The mechanism of BPPV is suspected to be otoconial debris – which results from aging changes – moving in the semicircular canals and creating hypersensitivity to bodily movement [10, 38, 39]. Despite aging-related elements, BPPV is considered a separate, narrower condition than the breadth denoted by presbystasis.

Clinical Implications

Presbystasis is extremely common and thus an important clinical consideration throughout the surgical trajectory [13]. It creates risk of both minor and serious injury as well as discomforting sensations throughout the process of surgical care. Individuals affected by presbystasis then carry a clinically important risk of falling at some time during surgical treatment. Individualized plans of care should include attention to preoperative condition and reconditioning efforts as possible, as well as modification of the hospital environment and promotion of visual and proprioceptive cues [34]. Aspects of surgical care, including pharmacotherapy such as anesthetics, analgesics, and diuretics, may interact with altered balance and promote the potential to fall. As with presbycusis, elective surgery affords the opportunity for screening through preoperative history and physical assessment to generate appropriate referrals to otolaryngology and physical therapy [34]. These referrals aim for specialized assessment and discrete diagnosis along with treatment designed to mitigate the effects of presbystasis and promote visual and proprioceptive cues with spectacles, well-fitting footwear, and similar interventions. In emergency surgery, efforts to modify the hospital environment, provide compensatory support and

supervision, use visual and ambulation aides, and integrate rehabilitative interventions for overall physical condition as well as vestibular accommodation are paramount.

The Aging Nose

Anatomy and Physiology

The nasal vault lies behind the external structures of the nose, through which air passes during respiration [40]. Inspired air enters through the nares. The nasal septum divides the vault in to two cavities, each of which contains three turbinates. Turbinates are rounded projections that extend the length of the cavity and labeled by position – superior, middle, and inferior. The space or valley below each turbinate is named for the turbinate above it. The paranasal sinuses drain into the meati. These sinuses, also labeled by location, are maxillary, frontal, ethmoid, and sphenoid. All the sinuses are lined with a specialized ciliated epithelium that secretes mucus and maintains mucosal flow with ciliary movement [41]. Together, the turbinates, mucus, and cilia insure humidification of inspired air and prevent gross and microscopic debris from entering the lower respiratory tract. The aging nose, like the external structures of the aging ear, is subject to cartilage collapse [40]. Few other changes in the nose are expressly linked to aging, though older adults may complain of more frequent rhinitis and sinusitis [42, 43]. Atrophic mucosa is a significant factor in these processes [41, 42]. The elderly may, as well, be more susceptible to nasal allergens and allergic rhinitis despite common clinical wisdom that allergen response declines with age [43].

The olfactory region is in the superior aspect of the nasal vault, a combination of olfactory and respiratory epithelial tissue [44–46] (see Figs. 43.10 and 43.11). Olfactory epithelium is organized into pseudostratified columnar shape with four cell types constituting this epithelium (viz. ciliated olfactory receptor neurons, sustentacular cells, microvillar cells of unknown function, and basal cells). Basal cells are the stem cell population responsible for differentiating and replacing lost olfactory receptor neurons [46]. Olfactory respiratory neurons transmit the signal from the odorant molecules to the central nervous system. Early in life, there is a balance between neurogenesis and the lifespan of the olfactory respiratory neurons. With aging, this process of neurogenesis degenerates and is no longer one of equilibrium in terms of maintenance of the type of the epithelium [44–46]. Additionally, there are increased patches of respiratory epithelium, representing a loss of the primary olfactory receptor neurons. The boundary between olfactory and respiratory epithelium becomes less well-defined with advancing age.

FIGURE 43.10 Olfactory neuroepithelium – sagittal view (reprinted from Wrobel BB, Leopold DA (2004) Smell and taste disorders. *Facial Plast Surg Clin North Am* 12(4):459–468, with permission from Elsevier).

FIGURE 43.11 Olfactory neuroepithelium – coronal view (reprinted from Wrobel BB, Leopold DA. Smell and taste disorders (2004) *Facial Plast Surg Clin North Am* 12(4):459–468, with permission from Elsevier).

Thus, age-related changes in olfactory function are multifactorial and encompass interactions among the composition of olfactory epithelium, decline in specialized cell populations, and decline in olfactory cilia [44, 45].

Olfactory Function

Presbyosmia, loss of the sense of smell with aging, can significantly affect safety and quality of life [46]. Loss occurs on a continuum and is more correctly labeled by degree: anosmia (absent olfactory function), hyposmia (decline in olfactory function), and dysosmia (distorted olfactory function) [47]. Hyperosmia is less commonly noted in older adults. Well over half of adults aged 65–80 years of age have major olfactory disturbances [44–46]. The potential implications of olfactory loss are significant and range from inability to perceive noxious odors that present threats to environmental or food safety to depression and anhedonia [46]. Nonetheless, many patients are unaware of olfactory changes with age, will have no clinical response, and are unlikely to report changes to clinicians [46, 48].

Clinical Implications

The aging nose presents few clinical ramifications for surgical treatment. Cartilage collapse in the very old may challenge the utility of nasal intubation (endotracheal and nasogastric) and should be considered by the anesthesiologist and the surgeon. Effects of presbyosmia in surgical treatment are also limited. Clearly, attention to patients' complaints with otolaryngologic and neurological referrals is critical. Abrupt or distinct anosmia, rather than being a manifestation of aging changes, may be a sign of Alzheimer's disease as well as possibly being a harbinger of Parkinson's disease [46, 49–52]. Additionally, given the intersections of the senses of smell and taste, presbyosmic patients may report disabling dysgeusia rather than altered olfaction specifically [48]. Further, these patients may be malnourished as a result of this complex of conditions with commensurate risk of immune dysfunction and impaired postoperative wound healing. Thus, preoperative assessment of nutritional status and referrals to an otolaryngologist and to a registered dietician optimize care of patients in elective surgery. The same consultations are warranted as soon as possible after emergent surgery if presbyosmia, dysgeusia, or consequent or multifactorial malnutrition is suspected.

The Aging Throat

Anatomy and Physiology

The anatomy of the larynx, the central anatomical component of the throat, comprises a cartilaginous skeleton, internal and external muscles, and a mucosal lining [53] (see Figs. 43.12 and 43.13). The larynx and pharynx sit below the nasopharynx and the oropharynx to form, with the oral cavity and the nasal structures, the upper aerodigestive tract. The thyroid cartilage and the cricoid cartilage are visible anteriorly, with the cricoid forming the lower bound and the hyoid bone the upper bound of the organ (see Fig. 43.12). The two arytenoid cartilages are visible posterolaterally (see Fig. 43.12). These cartilaginous elements of the skeleton form two joints in the larynx. The cricoarytenoid joint is superior and the cricothyroid joint inferior at the posterior of the larynx. The vocal folds – or cords – attach to the arytenoids and form the glottis as their aperture (see Fig. 43.13). The cricothyroid muscles and the smaller vocalis muscle are responsible for tension and relaxation of the vocal folds. The posterior cricoarytenoid is the abductor of the vocal folds. The lateral cricoarytenoid, thyroarytenoid, and arytenoideus muscles adduct the vocal folds.

Branches of the inferior and superior thyroid arteries supply the larynx. Motor innervations arise from the cranial

FIGURE 43.12 The larynx – lateral view (reprinted from Marchant W (2005) *Anatomy of the larynx, trachea and bronchi*. *Anaesth Intensive Care Med* 6(8):253–255, with permission from Elsevier).

division of the accessory nerve, which travels with and therefore is clinically indistinguishable from the vagus nerve. The recurrent branch of the vagus nerve supplies almost all laryngeal muscles, save for the cricothyroid muscle that is innervated by the external laryngeal nerve. Sensory innervation is achieved through the internal laryngeal nerve above the vocal folds and the recurrent laryngeal nerve below them. These are branches of the vagus nerve that also supplies parasympathetic innervation.

The skeletal and muscular structures together create the form of the larynx [53]. In cross section, from the superior most aspect, the larynx begins with the aryepiglottic fold, the vestibule and the vestibular fold, the ventricle, the vocal fold, and the infraglottic cavity. The larynx is lined with mucosal tissue that maintains the humidity of inspired air during respiration and phonation, the central functions of the larynx. The mucosal lining also contributes to the pitch produced by the vibrating vocal folds when inspired air is drawn over them, creating phonation [53]. The epiglottis, which is critical to the laryngeal component in deglutition, sits behind the thyroid cartilage. The aryepiglotticus, thyroepiglotticus, and thyroarytenoid muscles close the larynx entirely, as during deglutition.

The pharynx begins behind the nasal structures, at the base of the skull, and extends to the cricoid cartilage [54] (see Fig. 43.14). At this point, the pharynx becomes the cervical

FIGURE 43.13 The larynx – coronal view. (reprinted from Marchant W (2005) *Anatomy of the larynx, trachea and bronchi*. *Anaesth Intensive Care Med* 6(8):253–255, with permission from Elsevier).

FIGURE 43.14 The oropharynx and pharynx – sagittal view (reprinted from Craven J (2005) *Anatomy of the naso- and oropharynx*. *Anaesth Intensive Care Med* 6(7):217–218, with permission from Elsevier).

portion of the esophagus. Unlike the complex larynx, the pharynx is a muscular tube. The outer anatomy of the pharynx is composed of three circular, skeletal muscle constrictors – superior, middle, and inferior. The inner muscular layer of the pharynx is composed of the stylopharyngeus, palatopharyngeus, and salpingopharyngeus muscles. Together these muscles support the successive contraction necessary to move a food bolus to the esophagus. In addition, the inferior constrictor maintains tone to function as a sphincter to limit air entering the digestive tract. Like the larynx, most motor innervation is supplied by branches of the accessory nerve. The stylopharyngeus muscle is the sole exception as it is innervated for motor and sensory function by the glossopharyngeal nerve. The glossopharyngeal nerve is the sensory supply for the pharynx, while the parasympathetic supply arises from branches of the vagus nerve. The functions of the pharynx and larynx require neuromuscular coordination and feedback for functional respiration, phonation, and deglutition, including protection of the respiratory and digestive tracts [54, 55].

The oral cavity is delimited anteriorly by the oral labia [54] (see Fig. 43.15). The muscles that control the lips and thus the oral cavity aperture are levator labii superioris, depressor anguli oris, and risorius. The cavity is lined with mucosal epithelium that covers the buccal surfaces and the hard palate. The transition to the soft palate marks the transition to the pharynx. Several muscles form the palatal aponeurosis: tensor veli palatini, levator veli palatini, palatopharyngeus, uvulus, and palatoglossus. German and Palmer [54] note that these muscles coordinate to open or

close the airway during swallowing and to contribute to deglutition itself by altering the shape of the pharynx. The oral tongue and 32 permanent teeth are contained within the oral cavity. The muscles of the oral tongue include the extrinsic muscles – genioglossus, hyoglossus, styloglossus, and palatoglossus – which are innervated by hypoglossal and the vagus or accessory nerves and the intrinsic fibers – vertical, transverse, and longitudinal which are innervated by the hypoglossal nerve. The neuromuscular coordination of tongue movement is complex and involves the lingual nerve, branches of the glossopharyngeal nerve, and the internal laryngeal nerve in a minor capacity. The tongue, as well as aspects of adjacent structures like the soft palate, is covered with specialized papillae [56]. These papillae are found in fungiform, foliate, and vallate morphologies with a precise distribution over the tongue, creating the peripheral taste anatomy [48, 56]. Taste sensation is innervated by a branch of the facial nerve, the glossopharyngeal nerve, and the internal laryngeal nerve [48]. The muscles of the oral floor form the inferior boundary of the oral cavity and include digastric, mylohyoid, and geniohyoid muscles. Dentition arises from the maxilla and mandible, elements of the oral skeleton. The functions of the oral cavity are supported by adjacent structures without which mastication and transit of food are not possible. These components of oral function are the salivary glands, including the parotid, submandibular, sublingual, and minor salivary glands; the nasal structures, most importantly the olfactory epithelium with its direct contribution to chemosensation; and the muscles of mastication, temporalis, masseter, medial pterygoid, and lateral pterygoid [54].

Ageing Changes in Voice Function and Swallowing

Voice Function

Presbylarynx is the result of muscular atrophy and decreased elasticity in the muscular and skeletal components of the larynx [57, 58]. In fact, these changes begin early and are noted on examination as early as the fifth decade of life though functional effects are not noted by the individual potentially until the eighth or ninth decade of life if ever. Bowing of the vocal fold is the primary physical change. This bowing alters the aperture of the folds and results in incomplete closure causing a glottic gap. Other ligamentous and cartilaginous structures of the larynx are further altered with advancing age. The cartilaginous skeleton and joints ossify and the joints may become arthritic and dysfunctional. Microscopically, fibroblasts in the lamina propria may senesce and lose elasticity [17]. The lamina propria becomes denser as it produces less hyaluronic acid and more

collagen. These changes alter the vibratory characteristics of the vocal folds [17, 53].

The voice changes experienced by older adults with advancing age are termed presbyphonia [17, 53]. The alterations in the laryngeal skeleton and function of the vocal folds include poor projection, shorter duration of phonation, and vocal roughness or instability. Importantly, presbyphonia is a diagnosis of exclusion [53]. It is the least common cause of vocal disturbance among older adults, accounting for approximately ten percent of voice complaints. More commonly, in order of incidence, older adults will suffer benign polyps, malignant vocal cord lesions, vocal cord paralysis, or functional dysphonia [53]. Neurodegenerative conditions, such as Parkinson's disease, also frequently create significant vocal dysfunction [53].

Oropharyngeal Function

Oropharyngeal function in later life is less a matter of tissue senescence [11, 54, 59, 60]. Dysfunction emerges more often as a product of "wear and tear" in the oral cavity with contributions of effects of local and systemic disease as well as treatment side effects of discrete functions like salivation [59]. Evidence points increasingly to decreased edentulism and increased functional dentition (i.e., 20 or more teeth) among older adults in both community and residential settings. Taste sensation likely remains relatively robust in the absence of pathology or significant presbyosmia [48]. Notably, as many as a third of all older adults experience xerostomia [60]. Nevertheless, age-related changes in salivary production are often indistinguishable from primary salivary disease and the contributions of medications with antihistaminergic and anticholinergic effects. Percival [61] notes that microbial flora of the oral cavity remain stable with age, all other factors being equal. However, conditions like xerostomia, changes in dentition and oral hygiene, and significant local disease, such as oral premalignant and malignant lesions, and systemic diseases including acute problems such as pneumonia and chronic concerns like Alzheimer's disease and Parkinson's disease may alter oral flora, salivary production, and functional capacity to perform hygiene [59–61]. As a result, oropharyngeal dysfunction among older adults is most often a complex and progressive cycle of direct and indirect functional changes [61]. Importantly, specific age-related alteration in taste is rarely noted, though Fukunaga and colleagues suggest that loss of taste perception may play a role in dysgeusia [62]. Dysgeusia is more likely the result of presbyosmia or the effects of disease or its treatment that impairs olfaction, tastes, or both or effects contributory functions like salivation [11, 48, 54, 60]. Hall [11] notes that age-associated neuromuscular decondition-

ing or disease may result in oropharyngeal dyskinesia. There are resultant and often severe risks of dysphagia and aspiration, especially in stroke or with progressive neurodegenerative disease.

Clinical Implications

Presbylarynx and presbyphonia have circumscribed effects on surgical treatment. For patients who are distressed by presbyphonia, anxiety about being misunderstood or subjected to discrimination because of the "old" quality of their voices is likely real and thus a warranted concern. Attention to communication, discrete consideration of the basis for clinical decisions, and appropriate referrals to an otolaryngologist are important elements in addressing presbyphonia. Concerns about endotracheal intubation for surgery, given skeletal changes in the larynx, are probably theoretical and lack substantive evidence. However, rigidity in the cartilage and joints may offer some risk in the most affected elders, though the more clinically prominent issues of cervical spinal arthritis and kyphosis outweigh potential laryngeal rigidity. Skillful intubation with tacit recognition of laryngeal fragility is thus important in the absence of detailed and clinically relevant data. Nevertheless, postintubation voice changes may affect communication and comfort.

Oropharyngeal dysfunction among older adults poses significant risk and threats to surgical treatment. Such dysfunction may arise from aging changes in the anatomy and physiology of swallowing, dental pathology, comorbid disease that affects neuromuscular coordination, or any combination of these factors [8, 19, 63]. Side effects of intubation and anesthesia as well as postoperative healing, as it creates fatigue and saps functional reserves, may breach thresholds of functional compensation for dysphagia and aspiration. Elective surgery affords opportunity for integration of an interdisciplinary plan of care to assess and address for age-related and, more importantly, age-associated disease effects. Essential referrals include routine dental prophylaxis and treatment of dental caries and gingival disease that might affect tooth retention during the postoperative period as well as xerostomia; otolaryngologic and speech language assessment and intervention for diseases and dysfunction in deglutition, respiration, and phonation; and nutrition consultation and intervention to optimize visceral protein and overall nutritional status. These referrals are likely to be more successful given continuous collaboration with a particular patient's primary care provider. Comprehensive patient and family education further supports an effective plan of care and can be delivered by nurses on an outpatient basis before surgery, integrated into the inpatient care plan, and then reinforced during inpatient or outpatient rehabilitative postoperative follow-up.

Summary

Aspects of aging anatomy and physiology in the ears, nose, and throat have manifold and often consequential implications for surgical treatment of older adults. In the ears, presbycusis affects communication that results in possible problems in decision making and participation in perioperative care. Presbystasis is even more consequential as it is extremely common and results in significant risk of falls with the additive effects of anesthetics, analgesics, and diuretics, along with other postoperative interventions. Conversely, presbyosmia has little direct influence on surgical treatment save for implications of malnutrition when combined with the likelihood of dysgeusia and problems with food safety as a general concern. Presbyphonia conveys intermediate risk in surgical care for older adults. Older adults with noticeably affected voices may have difficulty in communication, both because of audibility and because of ageist discrimination for an “old” and infirm sounding voice. Finally, older adults with age-associated dental problems and acute or chronic disease that impinge upon neuromuscular coordination of the oropharynx are at significant risk for dysphagia and aspiration. The results of age-related functional changes in the anatomy and physiology of the ears, nose, and throat require thoughtfully integrated interdisciplinary surgical care. Knowledge of changes and functional implications is a rapidly evolving area of basic science and clinical investigation. Thus, surgeons can lead integration of a comprehensive plan of care that includes targeted referrals to specialists, preoperative preparation when possible, postoperative rehabilitation, and clear, consistent communication with patients, their family members, primary care providers, and other members of the interdisciplinary team. Modifications to the hospital environment that account for common sensory-perceptual and vocal changes, as well as ongoing patient and family education, further support successful care of the older surgical patient.

Chapter 44

Geriatric Dysphagia

Neil N. Chheda, Gregory N. Postma, and Michael M. Johns

Introduction

Dysphagia, literally difficult or disordered eating, can refer to numerous difficulties with swallowing. The normal swallow consists of introduction of food into the oral cavity and its subsequent passage through the pharynx and esophagus into the stomach. Disorders of swallowing may be found along any point during this passage. A recent survey found that approximately one-third of independent, noninstitutionalized, elderly Americans reported a problem with swallowing [1]. In the year 2000, there were 35 million Americans over the age of 65 which represented 12.4% of the total population. By the year 2050, this population group is projected to number over 86 million and comprise over 20% of the total population [2]. With the “graying” of the American population, the prevalence of dysphagia is expected to increase.

Effects of dysphagia range from reduced enjoyment of meals to embarrassment at meals with resultant social isolation that can progress to depression. Life-threatening consequences include dehydration, weight loss, choking, airway obstruction, and aspiration pneumonia [3]. Pneumonia is currently the sixth leading cause of death. Aspiration pneumonia is the most common cause of death in patients with dysphagia secondary to a neurological condition [4].

After hospitalization, less than 2% of those under the age of 65 but over 20% of those over the age of 65 were discharged to a long-term care institution [5]. Analysis of this data showed that approximately 60% of nondysphagic stroke patients were discharged home compared with 21% of dysphagic stroke patients [6]. An estimated 60% of nursing home residents have dysphagia. Autopsy studies reveal that pneumonia is the cause of death in one-third to one-half of all deaths among nursing home residents [7].

Numerous etiologies exist for the increased incidence of dysphagia among the geriatric population. Studies have identified age-related changes to the normal swallow mechanism that result in a “slower” swallow with reduced sensation and less ability to compensate. Disease processes that affect swallowing, such as stroke and Parkinson’s disease, are more prevalent in the geriatric population. In addition, social, psychological, and environmental changes occur, often in the setting of meal time activities.

Swallowing Physiology

The normal swallow process can be subdivided into three major phases: oral, pharyngeal, and esophageal. Of these, only the oral phase is under voluntary control. The oral phase is subdivided into an oral preparatory and oral transport phase where the food bolus is prepared into the proper consistency. During the pharyngeal phase, food is transported to the esophagus while the airway is protected from aspiration. The esophageal phase allows food to enter the remainder of the gastrointestinal system for digestion.

Prior to the swallowing process, the feeding process must occur – the voluntary delivery of food to the oral cavity. The individual requires the necessary cognition for food preparation and ability to schedule meal time. An intact extremity with proper coordination is needed to transport the food into the oral cavity. A functioning oral cavity is needed to receive the meal which requires the ability to open the mouth and coordinate the jaws and lips to receive the food.

The oral preparatory phase begins after the introduction of food into the mouth. The tone of the lips provided through the orbicularis oris musculature provides oral competency by preventing anterior spillage of the food bolus. Flavor and pleasure from eating are also derived during this phase. This phase can be voluntarily terminated if the taste, temperature, or consistency is not enjoyable. Through the coordination of the facial muscles such as the buccinator, the muscles of mastication (temporalis, medial and lateral pterygoid, and masseter), the tongue, the soft palate, and the teeth, the food

M.M. Johns (✉)

Department of Otolaryngology, Emory University School of Medicine, Emory University Hospital, Emory Voice Center, Atlanta, GA, USA

bolus is positioned and crushed into the appropriate texture and size for further handling. While the facial muscles are innervated by the facial nerve (cranial nerve VII), the muscles of mastication receive efferent signals from the trigeminal nerve (cranial nerve V). The tongue (cranial nerve XII) manipulates the bolus while the anterior movement of the soft palate (cranial nerve X) prevents premature passage of the food bolus while also opening the nasopharynx to increase the nasal airway.

After the food bolus has been adequately prepared by being chewed and mixed with saliva, as determined by various chemoreceptors and mechanoreceptors (cranial nerves V, IX, and X), the second part of the oral phase begins. Like the oral preparatory phase, the oral transport phase is under voluntary control. Through tongue manipulation, the food bolus is directed toward the oropharynx. After passing through the region of the faucal arches, branches of the glossopharyngeal and vagus nerve are stimulated and initiate the involuntary pharyngeal phase. Normal oral transport time ranges from 1 to 1.25 s regardless of viscosity [8].

While the nasopharynx is opened during the oral preparatory phase, actions of the velopharyngeal muscles during the pharyngeal phase close the nasopharynx to prevent nasal regurgitation. Posterior movement of the tongue and depression of the jaw direct the food bolus into the vallecula, the region between the base of tongue and epiglottis. Contraction of the suprahyoid muscles results in the superior and anterior movement of the larynx. By acting as a fulcrum, these actions invert the epiglottis and direct the movement of the food bolus from the vallecula into the two laterally located pyriform sinuses. The coordinate actions of the superior, middle, and inferior constrictor muscles result in an organized pharyngeal “squeeze” that moves the bolus in a superior to inferior direction through the pharynx. Mechanoreceptors, particularly of the tonsil pillars, stimulate the pharynx to continue to contract until the bolus has completely passed. The pharyngeal phase ends with passage of the food bolus through the upper esophageal sphincter (UES).

One of the primary objectives of the pharyngeal phase is the movement of food from the pharynx to the esophageal inlet while preventing passage of the bolus into the airway – aspiration. Mechanical defenses of the airway include the closure of both the true and false vocal folds, the inversion of the epiglottis over the laryngeal inlet, and the superior displacement of the larynx. Most frequently, respiration stops during the pharyngeal phase.

The UES is a manometrically defined region that is composed of the cricopharyngeus muscle, portions of the inferior pharyngeal constrictors, and the superior portion of the circular esophageal muscles. The cricopharyngeus is tonically active and in a “closed” state. Additional functions of the UES are the prevention of esophageal reflux and excessive air swallowing (aerophagia). The UES is opened through a

five step process beginning with an inhibition of the tonic contraction. Elevation of the hyoid laryngeal complex results in passive opening. Passage of the food bolus distends the UES with a subsequent collapse when the bolus passes through. Finally, active contraction leads to closure of the UES.

Like the pharyngeal phase, the esophageal phase is under involuntary control. Two layers of muscle are present in the esophagus – an inner circular layer and an outer longitudinal layer. While skeletal muscle predominates in the proximal esophagus, in the distal esophagus smooth muscle is the main form. The lower esophageal sphincter marks the distal extent of the esophagus. Stimulation from bolus distension leads to lower esophageal sphincter opening through vagus nerve efferents. The food bolus normally passes through the esophagus into the stomach in 8–10 s.

Three primary patterns of esophageal peristalsis have been noted. Primary peristalsis is the peristaltic wave triggered by the brainstem swallowing center. Secondary peristaltic waves are induced by esophageal distension, retained food bolus, refluxate, or swallowed air. They serve to clear the esophagus of reflux or retained food bolus. Tertiary contractions are noncoordinated, dysfunctional contractions. These contractions are nonperistaltic and have no known physiologic role.

A complex system of neural coordination governs the swallow process. Areas of the cerebral cortex, particularly the precentral and inferior frontal gyrus, modulate the oral and pharyngeal phase. The brainstem provides primary coordination of swallowing and a normal swallow is possible in the absence of any cortical stimulation [9]. Though neural control centers and pathways are located in both sides of the cerebral cortex and brainstem, transcranial magnetic stimulation has shown asymmetrical cortical representation [10, 11]. Seventy-five percent of cases of oropharyngeal dysphagia have a neurological cause [12]. Esophageal contraction propagation receives input from both the brainstem as well as from local neural feedback through the myenteric plexus of Auerbach located within the wall of the esophagus. Primary peristalsis is from the vagal nucleus while secondary peristalsis is under esophageal control.

Age-Related Changes to Swallowing Mechanism

Globally with aging, there is decreased striated muscle fiber size, sarcopenia, with muscle tone decreasing between 20 and 25% [13]. In the alimentary system, changes in connective tissue result in decreased tensile strength that may lead to the development of diverticula. Particularly in the tongue, these changes are accompanied by an increase of fatty and

connective tissue resulting in decreased strength and size. Osteoporosis and degenerative bony changes may alter cervical posture. For those patients who become edentulous, atrophy of the alveolar bone develops with reduced masticatory forces. Decreased salivary production affects bolus formation and manipulation. These changes in the oral phase do not often lead to significant difficulties as patients are able to modify their food intake to meet their needs (Table 44.1).

Bolus control is affected by the normal aging process. As a result of these age-related changes, there is decreased masticatory strength, reduced facial muscle strength with poor cup drinking, and reduced tongue strength and coordination [14, 15]. Compared with younger subjects, elderly patients tend to hold the bolus more posterior prior to the swallow [16]. Additional tongue movements were needed along with a slower swallow [17]. Yoshikawa evaluated the effect of age in comparing study participants who were all dentate and nonaspirators. The analysis found that the frequency of premature loss of liquid and increased oral and pharyngeal residue were greater in those over the age of 80 compared with younger control participants. In addition, oral transit time, pharyngeal delay time, and pharyngeal transit time in the dentate elderly group were found to be longer than in the younger group [18].

During the pharyngeal phase, age-related changes have more consequence compared with those of the oral phase. Manometry has shown that the amplitude, duration, and rate of pharyngeal pressure waves are not significantly changed in the elderly [19]. However, compared with younger individuals, the elderly have longer pharyngeal swallowing times and multiple swallows per bolus [20]. Aspiration is more likely as there is a three-time higher likelihood to inspire following swallowing rather than expire or breath hold. Aviv

demonstrated a progressive increase in laryngeal sensory thresholds, believed to correlate with decreased laryngopharyngeal sensory discrimination that occurs with increasing age. The threshold values needed to stimulate the laryngeal adductor reflex for those greater than 61 years old were significantly greater than those between 20 and 40 years old and those between 41 and 60 years old [21].

Prior studies have suggested that reduced UES opening occurs with age [22]. More recent manometry studies, however, have shown no change or decreased resting tone of the UES [23]. Through primary peristalsis is often preserved, there is reduced secondary peristalsis causing decreased stripping of esophageal residue as well as an increase in the frequency of tertiary peristalsis [24]. Findings that manifest in the pharyngeal phase such as pooling of secretions in the pyriform sinuses may be due to changes in the esophageal phase, such as a stricture or poor motility.

Otherwise healthy individuals are usually able to compensate for the normal age-related swallowing changes without significant consequence. Certain disease processes with swallowing consequences, such as cerebrovascular accident and Parkinson's disease, occur with greater frequency in the elderly. Together, these normal age-related changes may put elderly individuals more at risk for dysphagia from other disease processes in a "two hit phenomenon." Medications, anatomical changes, and deconditioning may further contribute to the increased frequency of dysphagia seen in the elderly. The normal aging process often leads to a delay in bolus transit through the pharynx. Patients with COPD may be forced to inhale while the bolus is in the pharynx leading to aspiration. In addition, older patients may fatigue during eating and progress from a safe to an unsafe swallow.

TABLE 44.1 Common changes seen in the swallowing mechanism with aging

General
Sarcopenia
Connective tissue changes
Osteoporosis
Oral phase
Edentulous state
Loss of tongue strength/coordination
Reduced masticatory strength
Reduced facial muscle tone
Pharyngeal phase
Longer swallow time
More swallows per bolus
Reduced laryngopharyngeal sensation
Reduced bolus control
More likely to inspire during swallowing
Esophageal phase
Possible reduced UES opening
Decreased secondary peristalsis

Evaluation

History

Initial evaluation of dysphagia must include a careful history. In cases of a sudden onset, an etiology can often be identified such as stroke, acute illness, or intubation. However, there is often an insidious onset to dysphagia symptoms without a precise antecedent event. Questions should be asked about changes in diet, food consistency, number of meals consumed, and length of meals. A patient with feeding difficulties, which may be due to cognitive deficits, may eat frequent, irregularly spaced short meals, whereas patients with swallowing difficulty often have an increased meal time. Untreated dysphagia will ultimately lead to weight loss. However, in the initial period of recognized symptoms, some elderly patients may briefly experience a weight gain due to a change

in food consistency such as consuming high caloric supplements. Three symptoms that have identified in an ambulatory geriatric population that are associated with a history of swallowing disorders are (1) taking a longer time to eat; (2) coughing, throat clearing, or choking, before, during, or after eating; and (3) a sensation of food stuck in the throat [1].

Querying the consistency of the food causing the most difficulty may aid in identification of the underlying etiology. Solid food dysphagia has traditionally been associated with an anatomic obstruction such as a stricture or web. Those reporting liquid dysphagia frequently have an underlying neurological dysfunction affecting coordination, sensation, or function. In cases of an insidious onset, patients may change their diet consistency to alleviate symptoms and may not readily recognize a difficulty with swallowing. Food avoidance may be an early indicator of dysphagia. Symptoms such as coughing with meals may indicate the presence of laryngeal penetration or aspiration. The regurgitation of undigested foods may suggest the presence of a diverticulum. Pain with swallowing, odynophagia, is an uncommon findings and may suggest an underlying malignancy.

Particularly for those with liquid dysphagia, a thorough neurological history should be ascertained. Specific signs to review include changes in gait, handwriting, and other fine motor skills that may reveal a global neurological condition. The responses from family and caregivers often provide accurate answers.

The past medical history should be queried for the presence of prior gastrointestinal conditions. Decreased pulmonary reserve, such as with advanced COPD, may also decrease swallow reserve. Recent endotracheal intubation should be identified as laryngeal sensation may be altered. Laryngeal function may also be affected by prior pulmonary, cardiac, cervical spine or neck (i.e., thyroid) procedures. In an ambulatory population, a history of esophageal reflux was identified as the most potent past medical history variable that identified in those with swallowing disorders.

Physical Examination

The physical examination should include an orderly, site-directed examination with particular attention to strength, fatigability, and coordination. Directed examination usually begins with the oral cavity. The lips are assessed for the ability to produce a complete seal, oral competency. Lip closure force has been found to correlate with markers of dysphagia such as weight loss, drooling, and food becoming “stuck” in the esophagus [25]. The presence and quality of the teeth may affect the ability to handle solids. Denture plates may block mechanoreceptors of the palate affecting afferent signals. Asymmetric palate elevation may indicate vagal

dysfunction. The tongue is assessed for the range of motion. Fasciculation of the tongue may indicate other neurological disease. The degree of laryngeal elevation with a dry swallow should be evaluated. The quality of the voice should be assessed. A thin or wet voice may suggest a laryngeal pathology. Dysarthria of the voice may indicate a central neurological disorder. Fixed neck adenopathy may indicate a neoplastic process.

Neurological assessment should include a basic level of arousal and orientation. A directed cranial nerve exam should be conducted. Those with dysfunction of the facial or hypoglossal nerve may have difficulty with bolus manipulation. The “gag reflex” tests sensory components of the glossopharyngeal nerve and motor function of the vagus nerve. The gag reflex, however, is not a normal component of swallowing. With the exception of an acute stroke, the presence or absence of the gag reflex has not been correlated with the risk of aspiration [26, 27]. Over one-third of healthy adults without dysphagia have an absent gag reflex.

Functional examination of swallow, particularly in inpatients, often begins with the bedside swallow assessment. Bedside evaluation begins with evaluation of patient’s level of arousal, posture, voice quality, voluntary cough, and control of saliva. Patients are fed a small bolus and if successful are then given a larger and more complex bolus. Studies have demonstrated that bedside swallowing assessments may miss between one-third and one-half of significant aspiration seen on videofluoroscopy [28–30]. Leder and Espinosa found that while the sensitivity of the clinical bedside exam was 86%, its specificity was only 30%, and its false-positive rate was 70% [31]. The two most reliable signs from bedside swallow were reduced pharyngeal sensation and coughing with 50 cc water swallow [26].

Additional Studies

The barium swallow is a radiographic examination particularly useful for evaluating the mass occupying lesions of the pharynx and esophagus such as found with solid food dysphagia. The barium swallow aids in the identification of diverticulum as well as extrinsic compression such as from vascular structures. The density and consistency of the swallowed contrast material can be altered to aid in diagnosis.

The modified barium swallow (MBS) allows a dynamic evaluation of the swallow process (Fig. 44.1). This study is typically performed in a fluoroscopy suite with the collaboration of a speech-language pathologist and radiology personnel. Viewing of the fluoroscopic images allows for the evaluation of bolus movement and timing from the lips to passage through the LES. The MBS has traditionally been used as the gold standard for the evaluation of aspiration and

FIGURE 44.1 An image from a modified barium swallowing study demonstrating clear aspiration with barium entering the trachea.

FIGURE 44.2 An image from a flexible endoscopic evaluation of swallowing. Note green colored material entering the larynx (penetration) and passing between the vocal folds (aspiration).

penetration. Compensatory maneuvers and rehabilitation strategies may be included at the time of examination.

Flexible endoscopic evaluation of swallow (FEES) is an ambulatory procedure that can also be used to evaluate the swallowing function and compensation technique [32, 33] (Fig. 44.2). In addition, the FEES examination can incorporate sensory testing for additional information (FEESST). Examination begins with an endoscopic examination of the pharynx and larynx. Important findings include the presence of secretions and the status of vocal fold mobility. The patient

is asked to produce a high pitched sound during which the pharyngeal walls are evaluated for symmetric contraction termed as the “pharyngeal squeeze.”

After the endoscopic examination of anatomy is completed, the patient is fed various food consistencies, usually colored to enhance visualization. During the swallowing portion of the examination, a thickened fluid, such as applesauce, is used first as this is least likely to produce aspiration. After the swallow has been completed, endoscopy allows the assessment of bolus residue as well as laryngeal penetration (entry of food into the laryngeal inlet), regurgitation, or aspiration (entry of food below the level of the vocal folds). With an impaired swallow, food may accumulate in the hypopharynx, such as in the pyriform sinuses, and then overflow into the larynx in a delayed fashion. Food bolus that “clears” the UES but then re-enters the pharynx may be a sign of a Zenker’s diverticulum, UES dysfunction, or poor esophageal motility.

In addition to its diagnostic value, the FEES examination can be used to guide compensatory maneuvers. For some patients, the visual feedback provided by endoscopy is easier to interpret than when seen on the MBS examination. One major disadvantage of the FEES examination is the “white-out” that occurs during the actual swallow as contraction of the pharyngeal walls and movement of the epiglottis temporarily obscure visualization.

Sensory testing can be incorporated into the FEES examination. During the FEESST examination, which was introduced in 1995 by Aviv, a calibrated air pulse is applied to the laryngeal mucosa at the junction of the arytenoid and aryepiglottic fold [34]. In the setting of normal physiology, a sufficient air pulse will stimulate the superior laryngeal nerve and activate the laryngeal adductor reflex resulting in glottic closure through the recurrent laryngeal nerve. This is an involuntary reflex arc and can be tested in those with cognitive deficits. Normative data for threshold pressures have been collected.

The MBS and FEES examination each possess relative advantages and should be used as complementary exams. Advantages of the MBS include the ability to evaluate the entire swallow including the esophageal phase which is not directly seen on FEES exam. Hyoid and laryngeal elevation, UES opening, and the degree of posterior movement of the tongue are better seen on MBS. Extrinsic compression is more easily identified. Disadvantages of the MBS include the need for radiation from the fluoroscopy equipment as well as the need to transport and position the patient in the fluoroscopy suite. A study found that in patients who had a MBS and FEES performed simultaneously, FEES examination graded the degree of dysphagia more severely [35]. A prospective, randomized study found no difference in pneumonia incidence whether MBS or FEESST was used to guide diet and swallow management [36].

The FEES exam allows for the diagnosis of subtle anatomic findings of the oropharynx, hypopharynx, and larynx. Native secretion can be easily identified and differentiated from ingested material. Examination can occur at bedside without the need for coordination with radiology personnel. Food bolus that pools in the pyriform sinus can accumulate and “spill” over into the laryngeal inlet. While both the FEES and MBS exam may be used to assess rehabilitative strategies, the biofeedback of the FEES examination may be more easily interpreted by the patient.

Esophagoscopy may be required during the workup of dysphagia. Traditionally, sedation has been required for the endoscopy. Adverse cardiopulmonary events related to sedation constitute a majority of the complications related to traditional esophagoscopy [37, 38]. Transnasal esophagoscopy (TNE) has emerged as a viable alternative. TNE can be safely and effectively performed with only local anesthesia and without the need for sedation. Endoscopic findings are diagnosed as accurately with TNE as EGD [39]. While the biopsy size is significantly smaller due to a smaller working channel, there was no difference in diagnostic ability between TNE and EGD [40, 41]. As the patient remains awake during the exam, the patient may be asked to swallow water or applesauce during exam such that a functional evaluation may also be incorporated into the examination. Direct examination of the mucosa allows for the detection of anatomic obstructions such as webs, rings, and strictures as well as the presence of esophagitis from causes including reflux and infection.

Quantitative assessment of peristalsis requires the use of manometry. Peristaltic pressure waves can be assessed for amplitude as well as timing and coordination. Conditions such as achalasia, ineffective esophageal motility, hypertonic UES, and diffuse esophageal spasm may be diagnosed through the use of manometry. Elderly patients with esophageal dysmotility tend to report different symptoms than younger patients.

Etiology

Cerebrovascular accident or stroke is the most common cause of dysphagia in the elderly. Forty-five to sixty-five percent of poststroke patients experience swallowing difficulties within the first 6 months after infarction [42, 43]. Approximately 25% of all patients die from aspiration pneumonia within 1 year of the stroke [44]. Results of the Paul Coverdall National Acute Stroke registry showed that only 45.5% of eligible stroke patients underwent dysphagia screening during their hospitalization [45]. Larger stroke infarctions have been associated with greater swallowing deficits with infarctions of the subcortical and periventricular regions associated with poor

tongue coordination and oral-phase dysphagia [46–48]. In addition to motor deficits, dysphagia may be secondary to lack of laryngopharyngeal sensory detection. Nearly one-half of patient recover to premorbid swallowing status within 1 week of the stroke and nearly 90% resume normal oral intake within 6 months after the event [49]. Swallow rehabilitation has been shown to improve the function though a temporary nonoral-feeding method may be required (Table 44.2).

Parkinson disease is the most common neuromuscular disease to cause dysphagia. The disease process affects the ability to initiate and coordinate complex motor tasks. An increase in oral pharyngeal transit time and decreased tongue movements have been noted [50]. Despite improvement of limb motor function with dopamine therapy, dysphagia may not improve. Swallow dysfunction is a late manifestation of Parkinson’s disease typically diagnosed greater than 1 year after diagnosis [51].

In amyotrophic lateral sclerosis (ALS), initiation of the voluntary swallow is prolonged. Aspiration is a less common phenomenon as pharyngeal and laryngeal sensation remains intact. Swallow therapy has been beneficial though some may eventually progress to require nonoral-feeding methods [52]. Other neurological etiologies include traumatic brain injury, Alzheimer’s disease, multiple sclerosis, brain malignancy, and Huntington’s disease. Though rarely a presenting symptom, myasthenia gravis and muscular dystrophy may report dysphagia.

Medications may affect swallow function through several mechanisms. The most frequent mechanism is through xerostomia. Xerostomia is common with medications that have anticholinergic effects such as antihistamines, tricyclic antidepressants, neuroleptics, antiemetics, and antidiarrhea medications. Elderly patients in an inpatient setting who were given an antipsychotic medication were three times more likely to have swallowing dysfunction than an age-matched controls who were not taking an antipsychotic [53]. By affecting saliva production, xerostomia alters bolus formation and transport. Dehydration from diuretic use may worsen xerostomia.

Alteration of arousal level resulting in mental status changes may also affect swallowing and feeding function. Medications should be screened for sedative properties such as hypnotics, anxiolytics, muscle relaxants, and analgesics. Alcohol may compound sedative effect.

Medications may alter esophageal function. Particularly in those with xerostomia, this effect may be magnified as less saliva with its neutralizing sodium bicarbonate content is produced. Pill-induced esophagitis may cause odynophagia through four primary mechanisms [54]. Prolonged mucosal contact may result in a direct caustic effect such as is seen with clindamycin, potassium, alendronate, and quinidine. Esophageal pH may be altered through medications such as clindamycin, tetracycline, ascorbic acid, and iron resulting in an acid burn. Phenytoin may result in an alkaline burn. Doxycycline and nonsteroidal anti-inflammatory drugs may accumulate to toxic levels within the esophagus. Drugs such as calcium channel blockers, nitrates, and theophylline may result in relaxation of the lower esophageal sphincter and induce gastric reflux [55].

Pill-induced esophagitis may be diagnosed through esophagoscopy where a well demarcated ulcer may be seen surrounded by normal mucosa. The most common site of injury in the esophagus is the area posterior to the arch of the aorta which is a natural site of narrowing and an area of manometrically decreased peristalsis. Compensation strategies include taking medications with ample water, crushing pills or taking the medication in liquid form, avoiding a double swallow, and taking medications in an upright position [56].

Esophageal motility disorders may result in dysphagia symptoms. Manometry allows for a specific diagnosis. Achalasia refers to an aperistaltic esophageal body with elevated LES pressures. A characteristic “bird beak” pattern may be seen on barium esophagram. In contrast, patients with scleroderma will also have a nonperistaltic mid- and distal esophagus but with the absence of LES pressures waves. There are normal findings in the proximal esophagus. Diffuse esophageal spasm features at least 20% of uncoordinated, simultaneous contractions with some normal peristalsis. The mean pressures of the distal esophagus exceed 180 mmHg in “nutcracker” esophagus. Residual pressures

greater than 5 mmHg after swallowing suggest incomplete LES relaxation while LES pressures that do not exceed 10 mmHg indicate a hypotensive LES. Ribeiro et al. reported that when compared with younger patients, elderly patients were less likely to have normal esophageal motility and were more likely to have achalasia or diffuse esophageal spasm [57]. Among those with achalasia, as diagnosed by manometry, cough and dyspnea were more frequent complaints in the elderly than chest pain seen in younger patients [58]. A comparison of patients with known esophageal dysmotility found that elderly patients over 80 years old were more likely to report dysphagia as their main complaint and have significantly more complaints of dysphagia to solids and liquids than younger patients. Younger patients were more likely to report symptoms of heartburn [59].

The presence of an obstructing lesion should be suspected in those with solid food dysphagia. Esophageal webs have been found in the proximal esophagus, particularly in those with Plummer–Vinson syndrome (Fig. 44.3). Two forms of esophageal rings may be present. The less frequently seen Type A ring is a thick muscular ring found in the distal esophagus. These muscular rings do not respond well to dilation but may improve after botulism toxin injection. The Type B ring, also known as a Schatzki’s ring, is found at the gastroesophageal junction. Rings with an opening diameter <13 mm tend to be symptomatic. The Type B ring responds to dilation or disruption.

Reflux esophagitis is a prevalent disease process found in the geriatric population [60]. Elderly patient were less likely to report classic gastroesophageal reflux symptoms such as heartburn or epigastric pain than younger patients. Instead, symptoms such as anorexia and dysphagia were more common [61]. The duration of reflux episodes, possibly secondary to

FIGURE 44.3 Fluoroscopic image of an anterior esophageal web at approximately the sixth cervical vertebra.

impaired esophageal motility, has been shown to be longer in the elderly [62]. Proton pump inhibitor therapy remains the primary therapeutic agent.

Candida albicans is the most frequent cause of infectious esophagitis. Risk factors for the development of a fungal esophagitis include immunodeficiency, diabetes, steroid use, and impaired esophageal motility. *Candida* colonies can also be seen among nonimmunosuppressed individuals as well. Treatment involves either a topical or systemic antifungal agent. Frank ulceration of the esophageal mucosa is uncommon and suggests a concurrent viral infection such as cytomegalovirus.

Cricopharyngeal (CP) dysfunction may contribute to dysphagia symptoms in the elderly. The dysfunction may be due to functional or structural reasons. Functional CP dysfunction refers to the failure of UES relaxation and has been associated with brainstem infarction, traumatic brain injury, and other neurological degenerative diseases. Figure 44.3 demonstrates the failure of CP relaxation with obstruction, commonly referred to as a cricopharyngeal bar. Structural CP dysfunction results in improper opening of the UES, despite relaxation of the UES musculature (Fig. 44.4). Structural CP dysfunction is commonly found in postradiation patients [63]. In addition, large cervical osteophytes in the region of the UES can lead to obstruction (Fig. 44.5).

Within the UES, manometric studies have demonstrated that the area superior to the horizontal fibers of the CP muscle is exposed to the highest pressures. This region, known as the Killian's dehiscence, has a low density of muscle fibers compared with the rest of the UES. Outpouching of the pharynx in this area, secondary to elevated CP pressures, may result in the development of a Zenker's diverticulum [64] (Fig. 44.6).

FIGURE 44.4 A cricopharyngeal bar, in this case, resulting from the failure of cricopharyngeal muscle relaxation despite excellent hyolaryngeal elevation during swallowing.

FIGURE 44.5 Large anterior cervical osteophytes at the level of the UES impairing the passage of food material into the esophagus.

FIGURE 44.6 A large Zenker's diverticulum demonstrated as a pouch separate from the esophagus on barium swallow.

CASE STUDY

An 83-year-old man is accompanied by his 64-year-old daughter for a chief complaint of food “getting” stuck in his throat. He reports these symptoms have been present for years but have been getting worse. He states that recently at dinner, he felt like he was choking on a piece of chicken. His voice has gradually become softer over the years. He denies any weight loss or coughing with meal. His daughter, however, states that he coughs frequently after drinking his morning coffee. His past medical history is significant for a thyroidectomy 40 years ago, myocardial infarction at the age of 67, and COPD. He has a 50-pack-year history but quit smoking 5 years ago.

After a comprehensive physical examination, a laryngoscopy should be performed to evaluate the hypopharynx and laryngeal structures. Given his smoking history, the presence of a mucosal lesion would be concerning for a malignancy. The status of the vocal folds should be assessed in terms of mobility and “bulk” as “bowing” or atrophy of the vocal folds may be present. The pooling of secretions is highly suggestive of an obstruction or motility dysfunction.

Given his complaints of both solids and liquids, a FEES examination could be incorporated into the laryngoscopy. An alternative would be a MBS. Advantages of the FEES examination include the ability to perform without the need of a fluoroscopy suite and detailed views of the larynx. The MBS allows for the analysis of esophageal phase, particularly relevant given his solid food dysphagia. While both examinations allow for feedback, patient understanding of exam is usually greater with the FEES examination.

FEES examination demonstrated reduced pharyngeal muscular squeeze with retained secretions in the pyriform sinuses. Vocal fold mobility was normal and there were no masses present. Laryngeal sensation appeared reduced. MBS confirmed these observations and added the finding of mild esophageal dysmotility. There was no esophageal structures, diverticula, or masses noted on the esophagram.

The patient’s dysphagia was attributed to age-related changes and a dietary and behavioral intervention program was initiated by the speech pathologist. He was counseled to chew foods well, take small bites, and alternate liquids and solids. These interventions controlled the patient’s symptoms well.

Treatment

Two of the most important decisions that need to be made after the swallowing evaluation are whether the person is safe for oral swallowing and if so, with what consistencies and texture. Diets may be modified to exclude certain food consistencies. While diet modification may help prevent aspiration of ingested food, patients may remain at risk for aspiration of saliva or gastric refluxate. Swallow rehabilitation may include various methods to improve muscle function and coordination. These may include electrical stimulation, thermal stimulation, and muscle strength exercises. Additional strategies aim to optimize body posture and head position. Compensatory maneuvers, such as a supraglottic swallow, swallowing while breath holding, may improve function. Early intervention through swallow rehabilitation may allow a safe swallow and avoid or delay the need for nonoral feeding such as a gastrostomy tube.

In some patients, oral feeding may be considered unsafe and nonoral means of nutrition may be required. Two of the most common techniques are nutrition via a nasogastric tube or via a gastrostomy tube [65]. Nakajoh reported that the rate of aspiration pneumonia was significantly greater among dysphagic stroke patients who were fed orally versus those who had tube feedings, though the functional status of the orally fed group was higher [66]. No prospective, randomized trials

exist that compare oral versus PEG feeds in the advanced dementia population. However, analysis of the available data finds that among those with advanced dementia, tube feeds do not prevent aspiration pneumonia, prolonged survival, reduce the risk of pressure ulcers or infection, improved function, or provide palliation [67, 68].

Surgical Management

Because of the multifactorial nature of dysphagia in the older adult, surgery usually takes a secondary role to behavioral and dietary intervention. That being said, some specific problems can be well addressed with judicious use of surgery. The most common problems and the surgical techniques that can be utilized to treat them are summarized below.

Esophageal and Cricopharyngeal Narrowing

Strictures of the esophagus and cricopharyngeal segment are best initially managed with serial dilation in individuals who are able to tolerate anesthesia. The site of stricture can be visualized clearly on barium esophagram. Two important diagnostic considerations must be taken into account prior to

dilation. Most importantly, the surgeon must identify the etiology of the narrowed segment with esophagoscopy and rule out carcinoma. Either rigid or flexible esophagoscopy can be utilized. Flexible endoscopic imaging, however, is favored because it can be easily performed under sedation or even awake, using TNE [69]. Stenotic segments at the cricopharyngeal segment need to be carefully evaluated in the geriatric patient. In many of these cases, the narrowing noted on barium swallow results from inadequate hyolaryngeal elevation and failure of cricopharyngeal opening, rather than true stenosis. Once the cricopharyngeal segment is identified as the true source of stenosis, the surgeon must differentiate whether the segment is stenotic or whether cricopharyngeal spasm is present. Stenotic segments respond to dilation (again after neoplasm is excluded).

Cricopharyngeal spasm is best treated with either botulinum toxin injection or cricopharyngeal myotomy. Cricopharyngeal myotomy has been traditionally performed with an external approach through the neck. Recently popularized endoscopic approaches offer a more minimally invasive approach, but long-term outcomes are pending [70].

With regard to dilation, serial dilation can be performed blindly with Maloney dilators or over a guide wire with Savary dilators. It can be performed under sedation or under general anesthesia. Caution should be used with rigid esophagoscopy due to reduced flexibility of the cervical spine and cervical osteophytes in older individuals, which make exposure difficult and increase the risk for esophageal perforation. Radial dilation using balloon dilators passed under flexible esophagoscopy has become more commonplace because of this risk.

Zenker's Diverticula

Zenker's diverticula occur at a natural muscular dehiscence between the cricopharyngeus muscle and the inferior constrictor (Killian's Triangle). They are easily visualized on barium swallow, but, because of their location by the esophageal inlet,

they are harder to identify on endoscopy. The flexible endoscope tends to fall into the pouch, and the natural esophageal opening can be difficult to find. Due to the more frail nature of the esophageal wall in elderly individuals, extra caution must be taken with any resistance to endoscope passage.

The decision to treat a Zenker's diverticulum depends on the severity of symptoms and the size of the pouch. Individuals with minimal dysphagia and a small pouch can be simply monitored. More severe symptoms warrant intervention. The treatment of Zenker's diverticula can be approached either through an external or an endoscopic approach. The familiar external approach involves cricopharyngeal myotomy (the most important step) plus diverticulectomy or diverticulopexy. Over the past decade, however, most patients are being treated with an endoscopic stapling or CO₂ laser division of the common wall between the cricopharyngeus and the pouch [71]. A cricopharyngeal myotomy is thereby also performed (Fig. 44.7a, b). This approach is less invasive, equally effective, has fewer complications, and in many areas has become the standard of care for initial treatment. Thus, in most situations, it is a more suitable initial approach in the geriatric patient.

Glottal Insufficiency

With age, the vocal folds become more atrophic, and individuals may have reduced glottal closure and protection of the airway during swallowing. Vocal fold paralysis also occurs more frequently in the elderly, usually arising iatrogenically from anterior cervical spine, thyroid, and thoracic surgery, or from carcinoma of the lung involving the recurrent laryngeal nerve. The resulting glottal insufficiency can vary in severity. Some patients have minimal symptoms limited to mild vocal difficulties and some have severe symptoms with near complete loss of voice and severe dysphagia. A careful assessment of the patient's voice and swallowing symptoms as well as a detailed laryngeal examination with in-office endoscopic laryngoscopy help direct treatment.

FIGURE 44.7 Endoscopic picture of a Zenker's diverticulum. (a) Note the pouch inferiorly containing food material and the party wall between the pouch and the esophagus anteriorly. (b) Endoscopic stapling of the pouch simultaneously divides the cricopharyngeus and opens the pouch into the native esophagus.

Glottal insufficiency can be treated with voice and swallowing therapy from a speech-language pathologist, vocal fold injection augmentation, and laryngeal framework surgery. An initial approach with therapy makes sense, particularly for dysphagia symptoms, as most swallowing symptoms are improved with behavioral strategies, such as chin-tuck swallowing and head-turn swallowing [72]. Surgical options are reserved for cases when therapy fails or is likely to fail due to the severity of disease.

While Teflon vocal fold injection has been largely abandoned due to granuloma formation, other injectables are well suited to augment the vocal folds and improve glottal insufficiency. Collagen, carboxymethylcellulose, and hyaluronic acid injectables offer temporary augmentation in situations where function is expected to return. Calcium hydroxylapatite can be used for more durable results. Vocal fold injection can be performed either under general anesthesia or awake in the office, endoscopy suite, or even at the bedside. Although less precise, awake injection offers the elderly patient significant advantage in avoiding general anesthesia.

Laryngeal framework surgery refers to two main procedures designed to reposition the vocal fold permanently: type-I thyroplasty and arytenoid adduction [73]. These procedures offer precise vocal fold medialization and are performed in the operating room under light sedation. Voice improvement has been clearly documented and although there is less evidence, swallowing improvement also occurs [74].

Other Procedures

Laryngectomy and laryngotracheal separation are uncommonly used for profound aspiration [75]. Laryngectomy separates the respiratory tract from the digestive tract and essentially eliminates aspiration. Patients experience significant loss of quality of life largely related to the permanent tracheostoma and loss of laryngeal voice. Although voice can be restored through esophageal speech, tracheoesophageal puncture, and electrolaryngeal speech, laryngectomy is rarely performed for geriatric dysphagia. Laryngotracheal separation results in a similar effect as laryngectomy. Although theoretically reversible, voice rehabilitation is more difficult, and most patients can be managed with other techniques.

Tracheotomy is seldom performed for dysphagia alone, and should be considered a means for respiratory management. A tracheotomy does not prevent aspiration, and may, in fact, make aspiration worse [76]. However, patients with a tracheotomy have better pulmonary toilet and access to the respiratory system for suctioning and ventilator use. Because of these advantages, caution should be taken in decannulating patients with severe dysphagia.

Summary

Dysphagia is common in the geriatric patient causing significant functional and emotional quality-of-life impairment. Dysphagia in these patients is commonly multifactorial. Keen understanding of normal swallowing physiology and the common changes in the swallowing associated with aging are required in order to render an accurate diagnosis and therapeutic plan. MBS studies have been supplemented by flexible endoscopic evaluation of swallowing in the diagnostic armamentarium for these patients. Early involvement of speech-language pathology is critical in the assessment and intervention of geriatric dysphagia. Judicious use of surgery can positively impact dysphagia in select cases.

Chapter 45

Head and Neck Cancer in the Elderly

Babak Givi and Ashok R. Shaha

The head and neck region harbors a wide variety of malignancies. While the majority are easily treatable skin cancers, the bulk of mortality and morbidity comes from squamous cell carcinomas of the upper aerodigestive tract. Head and neck cancers account for approximately 3–5% of all cancers in the US. In 2007, more than 33,000 people were suffering from oral cavity, pharynx and laryngeal cancers in the US [1]. Moreover, head and neck cancers afflict the elderly population disproportionately.

The management of head and neck cancers has undergone major changes with the advent of new modalities such as organ preservation, partial resection, and microvascular free tissue transfers. In addition, new advances in chemotherapy and radiotherapy have offered new hope for patients. Few other areas of the body harbor as many critical organs as the head and neck. Consequently, diseases and treatments can cause significant morbidity and loss of critical function for the patient. While the results of surgery have improved quite significantly through the years, there are still major challenges in this field. One of the main problems is control of locoregional recurrence where there are few therapeutic options and treatment modalities can cause significant morbidity. Another important treatment aspect for head and neck cancers is the importance of multidisciplinary involvement. The roles of speech therapists, nutritionists, pain management, and maxillofacial prosthodontists can be as important as those of head and neck surgeons, medical oncologists, and radiation therapists. In spite of higher prevalence of head and neck cancers in the elderly population, there is paucity of data on the management and outcome of this group. Many myths and beliefs have prevented elderly patients from receiving standard therapies [2]. Traditionally, surgeons are reluctant to endeavor more aggressive surgical resections on this population. Furthermore, more recent trials of combined modality treatments such as concurrent chemoradiation, often have excluded elderly candidates [3]. This lack of data adds

to the challenges of head and neck cancer practitioner in planning optimal management of elderly patients. There is not always specific data or recommendations in management of different subsites of head and neck cancer in elderly. Based on evidence, these differences will be discussed in each section.

Clinical Anatomy of the Head and Neck

A basic understanding of anatomy is essential for all practitioners involved in the care of head and neck cancer patients. The upper aerodigestive tract is divided into the nose and paranasal sinuses, oral cavity, pharynx, and larynx (Fig. 45.1). Salivary gland anatomy will be discussed later in this chapter.

The nasal cavity consists of the space between the vestibule of the nose anteriorly and nasopharynx posteriorly. The lateral walls are bounded by turbinates and the nasal septum stands medially. The cribriform plate superiorly and hard palate inferiorly form the other two boundaries. The openings of frontal, maxillary, and ethmoid sinuses lie in the middle meatus between the middle and inferior turbinates. Tumor blockage of these openings can cause symptoms of sinusitis and opacification of sinuses on radiologic studies. The maxillary sinus is the most common site for paranasal sinus tumors. The maxillary sinus is divided by an imaginary plane (Ohngren's line) that runs between the medial canthus of the eye and the angle of mandible into the anteroinferior and superoposterior sections. Tumors of superoposterior section are more challenging, since treatment often requires management of orbital floor and skull base. Up to 15% of patients with maxillary sinus tumors will present with metastases to cervical node levels I and II. Sphenoid and frontal sinus tumors are quite uncommon.

The oral cavity is defined as the space between the vermillion of the lips and the junction of the hard and soft palate superiorly, and circumvallate papillae inferiorly. It is further divided into the vestibule (the space between the cheek and the teeth) and the oral cavity proper. Further subsites of

mouth include the lips, buccal mucosa, lower and upper alveolar ridges, retromolar trigone, floor of the mouth, hard palate, and anterior two-thirds of the tongue (oral tongue). Tumors of the oral cavity usually metastasize first to level I, then to level II and III of the cervical lymph nodes.

The pharynx is a muscular tube that communicates with the nasal, oral, and laryngeal cavities. It is divided into the nasopharynx superiorly, the oropharynx in the middle, and the hypopharynx inferiorly. The region between the skull base and the junction of the hard and soft palate is the nasopharynx. The oropharynx includes the base of tongue, vallecula, soft palate, tonsil, tonsillar fossa, and posterior pharyngeal wall. The hypopharynx consists of three areas: the pyriform sinus, the posterior pharyngeal wall between vallecula and cricoarytenoid joints, and the postcricoid area from the arytenoid cartilage to the inferior border of cricoid cartilage. Lymphatic drainage depends on the location of the lesion. While the nasopharynx drains into the upper part of the posterior triangle, the oropharynx drains to level II, and hypopharynx drains to levels II, III, and IV nodes. Base of the tongue lesion and those close to the midline have a propensity to metastasize bilaterally.

The larynx is divided into three parts. The supraglottic larynx extends from the hypopharynx to a horizontal plane passing through laryngeal ventricle. The epiglottis, aryepiglottic folds, arytenoid and false vocal cords make up the supraglottic larynx. This area has rich lymphatic drainage and lesions tend to metastasize early and bilaterally to the jugular chain. The glottic larynx, on the other hand, has very few lymphatic channels. This phenomenon, in addition to early symptoms due to hoarseness resulting from true vocal cord lesions, makes glottic cancer the most favorable of laryngeal cancers in terms of prognosis. Subglottic tumors are extremely rare. Most commonly, a glottic tumor extends to the subglottic area. Tumors involving the subglottic area tend to metastasize to the jugular chain and tracheoesophageal nodes.

A thorough knowledge of the anatomy and classification of lymphatic structure of the head and neck is of utmost importance to all practitioners of head and neck cancers. Cervical lymph nodes are the most common site of metastases from different head and neck cancers and also a common locus of recurrence. The most commonly used method for classification of cervical lymph nodes is the one originally

devised by the Head and Neck Service at Memorial Sloan-Kettering Cancer Center almost half a century ago and later adopted by American Head and Neck Society. The most recent revision was published in 2002 [4]. Since then minor refinements have been added to this classification [5]. In this system, the lymphatics of the neck are divided into six levels (Fig. 45.2). Level I is submandibular triangle lymph nodes; level II is upper jugular; level III is mid jugular; level IV is lower jugular; level V is posterior triangle lymph nodes; and level VI is anterior compartment, prelaryngeal, and paratracheal lymph nodes. Nodes in the superior mediastinum below suprasternal notch and above innominate artery are considered level VII. Levels I, II, and V are further subdivided into A and B sublevels. Level IA is submental lymph nodes; IB is submandibular; IIA is upper jugular lymph nodes below the spinal accessory nerve; IIB is upper jugular lymph nodes above the spinal accessory nerve; VA is spinal accessory nodes; and VB is transverse cervical and supraclavicular nodes. Over much of the past century, management of cervical lymph nodes revolved around extensive radical operations (radical neck dissection) with emphasis on removal of

all the lymph nodes and non-critical structures. Although this approach was effective in controlling the disease, it carried significant morbidity, the most well known being “shoulder syndrome” [6]. With improved understanding of the natural course of the disease and patterns of metastatic spread, this operation has evolved into a more selective and specific procedure (modified radical neck dissection and selective neck dissection) that removes only the most at risk lymphatic basins and tries to preserve the non-involved structures such as the internal jugular vein, accessory nerve, and sternocleidomastoid muscle. The details of lymphatic spread will be discussed later with each individual site.

Epidemiology and Risk Factors

Worldwide, head and neck cancers are among the ten most frequent cancers in men. More recent data analysis subdivides head and neck cancers into oral cavity and pharynx in one group and larynx in another group. Based on most recent global data from 2002, the 5 year prevalence of head and neck cancers is estimated at more than one million people for oral cavity and pharynx, and more than 450,000 for larynx cancer [7]. The prevalence of head and neck cancer was 1.4 times higher in less developed countries than developed regions of the world, which underscores the importance of developing and improving healthcare systems in these regions [8]. Globally, the highest rates of tongue and mouth cancer are reported from South Karachi, Pakistan for both men and women. Oropharynx and tonsil cancers were highest in Loire, France. Larynx cancer was highest in Basque, Spain and Sao Paulo, Brazil [8]. In the US, cancers of head and neck comprise about 3.3% of new cancer cases and 2% of all mortality from cancer, based on 2008 data [1]. Oral cavity and pharynx cancers are currently the eighth most common cancer in men in the United States. Head and neck cancers were 2.7 times more common in men than women.

In general, the incidence of head and neck cancers in US is declining; however, there is an observed increase in certain subpopulations. While the annual percentage change over a 30 year period among African American women was minus 1.38%, analysis of the 5 year period between 2000 and 2004 showed an increase of 3.18% [9]. Worldwide, the picture is heterogeneous. In eastern and northern Europe, oral cavity and tongue cancers are increasing in incidence, while declining for men in France and Italy. The incidence of head and neck cancers is increasing amongst women in Germany, France, and the UK, and for both men and women in Spain. China and India show decreases in incidence for both men and women, while Japan shows an increase in both. In Latin America, pharynx cancer incidence is on the rise everywhere except in Costa Rica. The incidence of larynx cancer is

FIGURE 45.2 Anatomic boundaries of six levels and sublevels of neck (From Archives of Otolaryngology Head and Neck Surgery. 2008 May;134(5):536–538).

mostly stable or decreasing worldwide, except in those few countries such as Japan, Denmark, Norway, and Spain (only in women) which show increases [10].

Head and neck cancers are much more common in the elderly. The median age of diagnosis for oral cavity and pharynx cancers is 62 and for larynx cancer is 64 years old [11]. As the population grows older, an increase in the number of patients with head and neck cancers is expected.

The most well known and well studied risk factors for head and neck cancers are cigarette smoking and alcohol consumption. At least 75% of head and neck cancers diagnosed in industrialized countries can be attributed to the combination of these two risk factors. Based on a meta-analysis of multiple studies worldwide, current cigarette smokers have a relative risk of 6.98 for developing larynx cancer, 6.76 for pharynx, and 3.43 for oral cavity cancers [12]. Former smokers are still at risk, although the risk is reduced depending on the years of abstinence. Smoking cessation around the age of 50 can reduce the risk by 50%, however, cessation at about 30 years of age brings down the risk by up to 90% [13]. Other forms of tobacco use have all been shown to be associated with an increased risk of head and neck cancer. Chewing tobacco is shown to be a risk factor for hypopharyngeal cancer in never-smokers in a study from India [14]. Passive (involuntary or secondhand) smoking at home or work is also associated with increased risk [15].

Alcohol seems to have a synergistic effect on the carcinogenic potential of tobacco. In addition, it has now been determined to be an independent risk factor for developing oropharynx, hypopharynx, and larynx cancers in never-smokers [16]. There are no meaningful differences in consumption of different types of alcohol and the risk is closely associated with frequency of alcohol consumption.

Viruses are known to be linked to the development of head and neck cancers. The most well known is Epstein-Barr Virus (EBV) and its association with nasopharyngeal cancer [17]. One of the more recently identified viruses is Human Papilloma Virus (HPV). HPV 16, a sexually transmitted virus, is now considered an etiologic factor for cancers of oropharynx. HPV has been attributed to the increase in incidence of oropharyngeal cancers in men between 40–59 years old and among non-smokers and non-drinkers. Currently, it is estimated that 20–25% of head and neck cancers are associated with HPV [18]. Cancers associated with HPV infection in general carry a better prognosis [19].

Other studied risk factors for developing head and neck cancers are oral carcinogens such as chewing betel nut with lime and catechu (in a quid of betel leaf called paan); dietary factors – there is an inverse ratio between consumption of fruits and vegetables and development of head and neck cancers [20, 21]; tooth loss [22], and even socioeconomic status [23]. Plummer–Vinson syndrome is associated with a

high incidence of postcricoid carcinoma in Europe, but this condition is quite rare in the US. There are a few occupations that are associated with a higher risk for head and neck cancer. Nickel refining is associated with laryngeal cancer, woodworking with cancers of nasal cavity and paranasal sinuses, and steel and textile workers with oral cancers. Genetically inherited syndromes such as Li-Fraumeni and Bloom can cause an increase in risk of head and neck cancers through increased susceptibility to environmental carcinogens. The significance of heavy exposure to carcinogens is less pronounced in cancers developing after seventh decade of life, as well as genetic mutations such as p53 [24].

Prevention

A large number of head and neck cancers can be prevented by modifications in lifestyle. Smoking cessation and limiting alcohol use show the greatest proven benefit. Limiting exposure to known toxins and maintaining dental hygiene are of potential benefit and feasible with minimal cost. Early intervention in documented premalignant lesions or second primary tumors after treatment may reduce the risk of further progression of disease. Vitamin A analogs and cis-retinoic acid were initially implicated with beneficial effects in preventing second primary tumors, but subsequent trials did not show any benefit [25, 26]. Because of the role of HPV in developing oropharyngeal cancers, vaccination against this virus might eventually become an accepted method of prevention.

Natural History of the Disease

Although diagnosis of most head and neck cancers is relatively easier than cancers of internal organs, only one-third of patients with oral cavity and pharynx cancers are diagnosed while the disease is still localized. About 44% of patients are diagnosed with regional disease and 14% with distant metastasis. Head and neck cancers in most cases follow an orderly pattern of progression. Squamous cell carcinomas arise from expansion of a genetically altered population of epithelial cells. Cell populations that have the potential of invasion will produce a number of proteases and also recruit local fibroblasts and macrophages to actively destroy the epithelial basal membrane [27]. After destruction of basal membrane there is the potential of regional and distant spread of tumor.

Based on a series of studies at Memorial-Sloan Kettering Cancer Center by Shah and colleagues [28–31], there is a

better understanding of patterns of lymphatic spread in head and neck cancers. Lymphatic spread happens in an orderly fashion in the majority of cases based on the location of tumor (Table 45.1). These patterns will be discussed separately for individual tumors. A number of characteristics are predictors of high probability of distant metastasis. Location of the primary tumor, initial T and N stage of the neoplasm, and the presence or absence of locoregional control above the clavicle are the most important ones [32]. Primary tumors of hypopharynx, oropharynx, and oral cavity of high T stage are associated with the highest incidence of distant metastasis. Patients with advanced nodal disease also have a high risk of distant metastasis, especially if the jugular vein is invaded or if soft tissues of the neck are extensively involved by the disease. The lungs are the most common site of distant metastasis and account for approximately 66% of cases [32]. Multiple pulmonary nodules are a very suspicious sign of distant metastasis in head and neck cancers; however, a solitary pulmonary nodule might make it quite difficult to distinguish a second primary in the lung from a metastatic lesion. Other sites include bone (22%), liver (10%), skin, mediastinum, and bone marrow.

Other less frequent patterns of spread might happen in selected subpopulations of patients. Tumors may spread along the nerves. This is particularly important in treatment planning for tumors that involve the mandible and might invade the inferior alveolar nerve. Direct invasion of other nerves in the neck, such as the hypoglossal, lingual, vagus and the sympathetic chain, may also occur by tumors in their vicinity. High grade tumors of parotid glands are well known to involve the facial nerve, especially when they are large and bulky. Benign tumors almost never cause paralysis even when they are of substantial size. Another route is aberrant metastatic spread. This is more common in patients who have undergone previous treatment for head and neck cancer. Patients after radiotherapy or radical neck dissection are at risk for developing aberrant metastases to the neck, and subcutaneous and cutaneous sites.

Second Primary Tumors

Head and neck cancer patients are at risk of harboring (synchronous) or developing (metachronous) a second primary tumor. Carcinogens such as tobacco and alcohol will affect the entire mucosal surface (field cancerization) [33] and the potential for malignant transformation remains even after removal of the noxious agent. These tumors can be a “true second primary tumor” with a different genetic fingerprint from the index lesion, or can be similar to the index tumor and arise from the premalignant lesions in the affected field (second field tumor) [34]. The annual incidence of second primary tumors is estimated to be approximately 4% [35–37]. Overall incidence can be as high as 27% in some reports [35] and as low as 9% in others [38]. These tumors are more common in younger patients [38] and the median time to presentation is around 3 years [38]. The prognosis of second primary tumors is not favorable [39]. This phenomenon necessitates the continued and long term close follow-up of the head and neck cancer patients.

Clinical Presentation

Many cancers of head and neck can be easily detected by patients or on routine examination. A chronic ulcer, new or persistent lump in the neck (Fig. 45.3), or new onset of hoarseness or dysphagia are such examples. In spite of these obvious alarming symptoms, two out of three head and neck cancer patients will be diagnosed in an advanced stage. This is in part due to patients’ negligence, but also reflects a component of delayed diagnosis in some cases [40, 41]. It is wise to consider the possibility of cancer in high risk patients with the new onset of symptoms, even when they are non-specific and vague. Symptoms and signs of head and neck cancer can be divided into two groups: local symptoms and generalized symptoms. The most common generalized symptom in head

FIGURE 45.3 Left neck mass. Slowly growing asymptomatic mass in an otherwise healthy elderly man. Final diagnosis was pleomorphic adenoma of left parotid gland.

and neck cancer is unexplained weight loss and usually happens late in the course of disease, or when it is related to difficulties in swallowing (dysphagia). Local symptoms depend on the location of tumor. Some tumors can be symptomatic at a very early stage. True vocal cord tumors are such an example. On the other hand, tumors of nasopharynx or hypopharynx can go undetected for long periods of time.

Nasal cavity and paranasal sinus tumors can remain undetected for extended periods of time. Most of the early symptoms such as nasal obstruction, rhinorrhea, and sinus congestion are quite similar to benign processes of sinusitis and allergic rhinitis. Late symptoms can include recurrent epistaxis, malar swelling, and diplopia that may happen in advanced stages of maxillary sinus tumors. Oral cavity tumors usually manifest with painful ulcerations, slurred speech, bleeding or an exophytic mass. Nasopharyngeal cancers may present in early stages with unilateral otitis media. Oropharynx and hypopharyngeal tumors can cause odynophagia, dysphagia, change of voice and, occasionally, airway obstruction. Laryngeal tumors can become symptomatic very early if they are located on vocal cords with changes in voice. Supraglottic and subglottic cancers can be relatively asymptomatic for long periods and show up later with dysphagia, odynophagia, and throat pain, or airway compromise.

Pain is not commonly associated with early head and neck cancers. Most commonly the pain is mediated by branches of the trigeminal, or glossopharyngeal and vagus nerves. Pharyngeal and laryngeal tumors can cause referred pain in ear through the glossopharyngeal and vagus nerves. Hypopharyngeal and base of tongue tumors also can cause ear pain through the nerve of Arnold (auricular branch of facial nerve). In advanced cases, patients may present with involvement of skin of the face and neck, mandibular involvement and loss of teeth, severe pain, and dysphagia, or

airway distress. Oral cavity tumors can erode through the subcutaneous tissue and skin and cause an orocutaneous fistula in advanced, neglected cases.

Diagnostic Workup

A complete history and physical exam is the first step in assessing any patient with suspicion for head and neck cancer. In obtaining the history, attention to symptoms and signs more related to head and neck tumors such as non-healing ulcers, sore throat, hoarseness or any voice changes is of obvious importance. In addition, asking about symptoms of otalgia, odynophagia, malar swelling, etc. that patients might not relate to their problem can reveal valuable information. General symptoms of malaise, fatigue, and weight loss should not be overlooked either. A complete exam of head and neck region involves several steps. Examination starts with a detailed survey of the region visually and continues by palpation of thyroid gland, neck, and bimanual examination of the floor of the mouth and base of the tongue. Mirror examination of the larynx and rigid or fiberoptic nasopharyngolaryngoscopy should be considered part of a routine head and neck exam. Certain areas are prone to be overlooked. The examiner should pay attention to the scalp, the nape of the neck, and the gingivolabial and gingivobuccal sulci. Most head and neck surgeons perform fine needle aspiration (FNA) of suspicious neck masses or thyroid nodules and salivary gland tumors as an office procedure, or they may be performed with ultrasound for better localization of the mass.

Imaging

Conventional X-rays, except for a Panorex of the mandible, are of very limited value in evaluating head and neck cancers and are not being used. A panoramic view of the mandible, however, is still valuable in assessing the possibility of mandibular invasion and also in preoperative evaluation for mandibular reconstruction with tissue transfer. A routine chest X-ray is performed in all head and neck cancer patients to rule out possible lung metastasis. Ultrasound is quite helpful in assessing neck masses, thyroid nodules, and in directing FNA of suspected lesions. The CT scan has become the mainstay of imaging in head and neck cancers. This modality provides excellent detail in deep tumors, relation of tumors with adjacent structures, and also in assessing the lymphatics of the head and neck (Fig. 45.4). The CT scan has superior resolution to MRI in assessing bony structures and should be obtained if there is any suspicion of bony involvement. MRI is commonly used and provides superior resolution in assessing

FIGURE 45.4 CT Scan image of advanced hypopharyngeal tumor. The image provides excellent details in extent of local invasion to adjacent structures. Note destruction of thyroid cartilage and invasion of larynx by tumor.

soft tissue, blood vessels, and nerves. It is not uncommon now to obtain both CT and MRI in assessing some head and neck tumors such as parapharyngeal space masses. Functional imaging using fluorodeoxyglucose-positron emission tomography (FDG-PET) is being used more commonly, especially for initial evaluation and follow-up of patients with malignant neoplasms. This modality is quite sensitive in detecting nodal spread or distant metastasis or both [42]. The Combined PET and CT provides more accurate results than each modality alone and is being utilized more often [43]. PET is especially helpful in the follow-up of patients and surveillance for recurrent disease.

Examination Under Anesthesia

Examination under anesthesia (EUA) is an important diagnostic and staging tool for the head and neck surgeon. This modality can be used in examining patients with oral cavity tumors with trismus, and patients with pharyngeal and laryngeal cancers. Rigid esophagoscopy is probably not needed in all patients, but in patients with hypopharyngeal tumors, a thorough examination of the esophagus is mandatory to determine the extent of the lesion. Bronchoscopy is also performed in select cases based on the judgment of the treating physician and the nature of the disease, such as subglottic tumors.

Similar to all areas of oncology an accurate tissue diagnosis is the cornerstone of the management. The role of head and neck surgeon in obtaining adequate and appropriate tissue is

as important as the pathologist that interprets the specimen. A few techniques are commonly used: punch biopsy, excisional biopsy, curettage, core-needle biopsy, and FNA. Each of these techniques is valuable in assessing certain types of lesions.

Punch biopsy is used quite commonly in mucosal lesions of head and neck. The preferred place is in the periphery of the lesion and the forceps commonly used is a cup forceps. A small sample usually is adequate to make a diagnosis. If a lesion is necrotic or appears to be infected, then the tissue should be obtained from a fleshy non-ulcerated section of the lesion. Small oral cavity lesions can be easily excised as a whole and submitted as an excisional biopsy with satisfactory margins. In cases of diffuse leukoplakia or erythroplakia, using vital dyes such as toluidine blue can be quite helpful to guide the surgeon to the most suspicious area. Incisional biopsy is used in lesions of the skin and soft tissue, and submucosal masses of the oral cavity and pharynx. Sampling irradiated tissue can be challenging since there can be edema or late radiation changes such as scarring and fibrosis. Asking for frozen samples to ascertain adequacy of tissue can be quite helpful in expediting the diagnostic process and avoiding extra procedures.

Fine needle aspiration was first described by Hayes Martin in 1930 [44]; however, out of fear of tumor implantation in the needle tract, it was not utilized extensively until the 1970s. Currently, FNA is the method of choice for evaluating most head and neck masses and is especially useful in assessing cervical lymphadenopathy [45], thyroid nodule, and salivary gland masses [46]. All practitioners dealing with head and neck cancer should be quite proficient in this technique. FNA biopsy interpretation requires a pathologist experienced in cytology.

The results of FNA biopsy can be interpreted as adequate or inadequate. If the sample is adequate, it can be metastatic squamous cell carcinoma, metastatic adenocarcinoma, metastatic thyroid carcinoma, or suspicious for lymphoma. An algorithm can be used in patients presenting with malignant features (Fig. 45.5). As valuable as FNA biopsy is in diagnosis, there are possible pitfalls and the clinician should interpret the results in the context of the all the available information. Further investigation, such as open biopsy, should be pursued if there are discrepancies between the results of FNA and the clinical picture.

Molecular Genetics and Pathogenesis

Over the past few decades major advances in understanding the genetic basis of development of squamous cell carcinomas of head and neck has occurred. The prevailing theories at this time propose a model of progressive genetic and

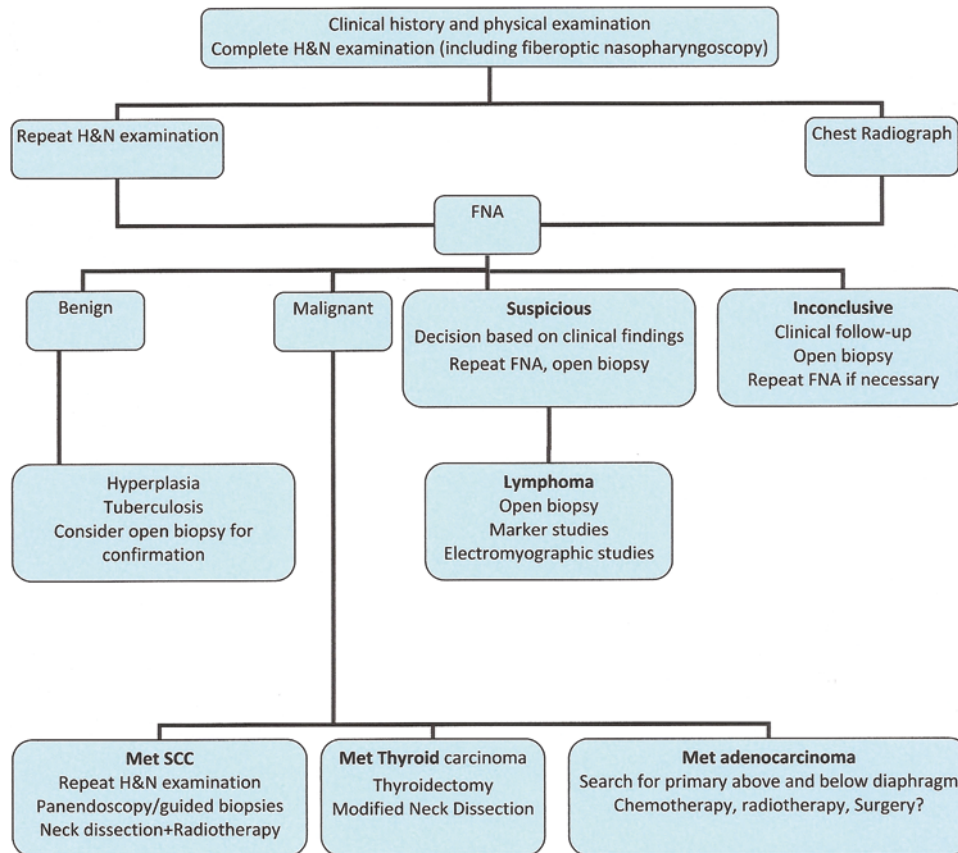

FIGURE 45.5 Algorithm for the management of cervical lymphadenopathy. (*H&N*) Head and Neck, (*FNA*) Fine Needle Aspiration, (*Met*) Metastatic, (*SCC*) Squamous cell carcinoma (Reprinted from

Shaha A et al (1986) Fine-needle aspiration in the diagnosis of cervical lymphadenopathy. *Am J Surg* 152(4):420–423).

phenotypic changes from normal mucosa to hyperplasia to premalignant lesion, carcinoma in situ and finally invasive cancer [47–49]. The genetic alterations in general cause activation of proto-oncogenes and inactivation of tumor suppressor genes. This can happen through deletion, point mutation, promoter methylation, or gene amplification. The most common genetic abnormality in premalignant lesions and head and neck SCCs is loss of heterozygosity in chromosomal region 9p21 [50, 51]. This abnormality is seen in 70–80% of cases. Loss of chromosomal heterozygosity (LOH) in 3p, 17p, 11q, and 13q are also seen in premalignant lesions and head and neck cancers with decreasing frequency [52–55]. LOH in chromosome 17p and p53 gene mutation are seen in 50% of head and neck cancers [56, 57]. Loss of 9p21 is considered an early event in progression of squamous neoplasia. This abnormality is seen in up to 30% of squamous hyperplasia [50, 51, 58]. On the other hand, abnormalities such as 17p loss and p53 deletion happen later in the process [59, 60]. Other abnormalities are associated with different tumor behavior. Amplification of 11q13 is associated with increased rate of lymph node metastases and overall poor prognosis [61–63]. Deletion of

the p53 gene has been associated with reduced survival after surgical treatment of head and neck cancers [64]. Interestingly this mutation is less common in head and neck cancer occurring after 70 years old [24].

Another relatively recent discovery is the role of Epidermal Growth Factor Receptor (EGFR) in head and neck cancers. EGFR belongs to the family of tyrosine kinase receptors. Binding of ligands results in activation of many downstream cascades that regulate cell proliferation, apoptosis, metastatic potential, and angiogenesis. EGFR can also be activated by other factors such as platelet derived growth factor and insulin-like growth factor. EGFR protein expression is seen in 90% or more of head and neck cancers [65] and many retrospective studies have shown that tumors that overexpress EGFR have a poor prognosis [66]. New medications (Cetuximab) have now been developed to target this receptor with successful results [67]. Angiogenesis is considered a fundamental process in the progression of malignant tumors. There are many proangiogenic and antiangiogenic factors that regulate this process. Vascular endothelial growth factor (VEGF) and its receptors have been extensively studied and their role in other solid tumors is established [68]. VEGF also

can be upregulated in head and neck cancers with prognostic significance [69]. Antiangiogenesis drugs are currently under investigation for use against head and neck SCCs.

Pathologic Classification

The majority of the upper aerodigestive tract is covered with squamous epithelial cells and therefore the majority of tumors in this area arise from these cells (squamous cell carcinoma). Other well known, but less frequent tumors can occur. Adenocarcinomas, melanomas, minor salivary gland tumors, sarcomas, and lymphomas have all been described to arise from this region.

In the spectrum of squamous cell malignancies, there are a few terms to describe premalignant and different varieties of malignant neoplasms. Oral epithelial dysplasia manifests itself in two dominant forms. Leukoplakia is defined as a predominantly white lesion that cannot be wiped away and cannot be characterized as any other specific disease entity on the basis of clinical features. Erythroplakia is defined as a red, velvety surface lesion. Lesions consisting of mixed white and red lesions are called “erythroleukoplakia” or “speckled leukoplakia”. In general, the risk of cancer arising from erythroplakia is considered higher than leukoplakia and in mixed lesions the red areas are more prone to transform to malignancy. Under the microscope these lesions show a range of histologic changes from nondysplastic epithelial hyperplasia to nuclear pleomorphism, increased mitoses, and architectural disturbances. The risk of developing malignancy in leukoplakic and erythroplakic lesions is dependent on the degree of dysplasia and other histologic factors. In lesions where dysplasia is present the risk can range from 11 to 36% depending on the length of follow-up [70–72]. Proliferative verrucous leukoplakia has been reported to have a malignant transformation rate as high as 70% [73].

Verrucous carcinoma is a rare and low grade variant of squamous cell carcinoma. It is more common in older men with a long standing history of smokeless tobacco abuse and comprises only 3% of oral cavity cancers in the US [74]. The appearance is quite unique and characteristic. It occurs most commonly in the buccal mucosa, the mandibular or maxillary vestibule, or the alveolar ridge and corresponds with the site of tobacco placement. The tumor usually appears as white, diffuse, thickened plaque with a distinct warty or papillary surface. Verrucous carcinoma is considered a low grade squamous cell carcinoma. It generally has a better prognosis due to its exophytic and slow growth pattern and highly differentiated nature. It can undergo dedifferentiation to more aggressive forms [75, 76]. The treatment is generally surgical excision, but primary radiotherapy has

also been successfully used. Sarcomatoid and basaloid varieties of squamous cell carcinoma on the other hand are more aggressive and have a higher rate of lymph node metastases. Basaloid carcinoma also has a high rate of distant metastases [77].

Other subtypes of squamous cell carcinoma in the head and neck are exophytic, ulcerating, and infiltrating. Infiltrating tumors usually have a worse prognosis. Tumors with lymphoid stroma are classified as lymphoepithelial carcinomas or lymphoepitheliomas. These are usually poorly differentiated tumors that most commonly occur in the nasopharynx and tonsil. They are quite radiosensitive.

A few other pathologic factors have been mentioned as determinants of prognosis. Presence of lymphatic, vascular, or perineural invasions are among those. Depth of invasion has been shown to predict a higher likelihood of cervical lymph node involvement [78].

Staging

Accurate staging of head and neck cancers is extremely important in determining the prognosis, treatment plans, and expected outcomes. It is recommended that all the information be gathered accurately and entered in the medical record as primary data. The staging systems have changed multiple times through history and without doubt will undergo more modifications. The advantage of retaining primary data lies in the fact that even when the classification systems change, one can accurately stage the patient in the correct group.

The staging system currently used for head and neck cancers is based on the sixth edition of AJCC-UICC TNM system [79]. The last modification was introduced in 2003 and significant changes were implemented [80]. This system is based on the characteristics of primary tumor (T), extent of nodal involvement (N), and status of distant metastasis (M). The T stage is primarily based on size and is site specific in head and neck cancer. One of the major changes in the new edition was subdivision of stage T4 to T4a and T4b, to differentiate between locally advanced tumors that are surgically resectable (T4a) and those that are not (T4b) (Tables 45.2–45.6).

The N stage is uniform for all head and neck cancers except tumors of nasopharynx and thyroid (Tables 45.7 and 45.8). M stage is based on absence (M0) or presence (M1) of distant metastasis (Table 45.9). The overall stage of the tumor consists of stages I–IV. Stage IV is now subdivided into three categories (IVa, IVb, and IVc) mostly based on the reorganization of T stage category. Stage I and II are considered early disease and prognosis in general is more favorable than advanced (III and IV) cancers (Tables 45.10 and 45.11).

TABLE 45.2 T staging for tumors of the lip and oral cavity

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4a	Moderately advanced local disease
Lip	Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face, that is, chin or nose
Oral cavity	Tumor invades adjacent structures only (e.g., through cortical bone [mandible or maxilla] into deep [extrinsic] muscle of tongue [genioglossus, hyoglossus, palatoglossus, and styloglossus], maxillary sinus, skin of face)
T4b	Very advanced local disease Tumor involves masticator space, pterygoid plates, or skull base and/or encases internal carotid artery

TABLE 45.3 T staging for tumors of the pharynx

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ

Nasopharynx

T1	Tumor confined to the nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension ^a
T2	Tumor with parapharyngeal extension ^a
T3	Tumor involves bony structures of skull base and/or paranasal sinuses
T4	Tumor with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit or with extension to the infratemporal fossa/masticator space

Oropharynx

T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3	Tumor more than 4 cm in greatest dimension
T4a	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible ^b
T4b	Very advanced local disease Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery

Hypopharynx

T1	Tumor limited to 1 subsite of hypopharynx and/or 2 cm or less in greatest dimension
T2	Tumor invades more than 1 subsite of hypopharynx or an adjacent site, or measures more than 2 cm, but not more than 4 cm in greatest diameter without fixation of hemilarynx
T3	Tumor measures more than 4 cm in greatest dimension or with fixation of hemilarynx or extension to esophagus
T4a	Moderately advanced local disease Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue ^c
T4b	Very advanced local disease Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

Source: Used with permission of the American Joint Committee on Cancer (AJCC®), Chicago, Illinois. The original source for this material is the AJCC Cancer Staging Handbook, Seventh Edition (2009) Page 69, published by Springer Science and Business Media, LLC, www.springerlink.com

^aNote: Parapharyngeal extension denotes posterolateral infiltration of tumor

^bNote: Mucosal extension to lingual surface of epiglottis from primary tumor of the base of the tongue and vallecula does not constitute invasion of larynx

^cNote: Central compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat

Principles of Treatment

Treatment of head and neck cancers is truly a multimodality, comprehensive, and team-based discipline. A multidisciplinary approach is the basic foundation of management of head and neck cancers. It requires considering many factors as diverse as tumor characteristics and patient's overall health to availability of resources and expertise. The most sensible treatment regimen is the one that is tailored to the patient's specific needs and circumstances. The treatment regimen will differ based on tumor site, depth of invasion, pathology, and clinical behavior. On the patient side, age, co-morbidities, risk factors, and patient cooperation and preferences are all very important factors. The availability of resources and expertise and the practicality of the treatment regimen are also significant determinants of the ultimate plan. Only a comprehensive approach involving all practitioners along with the active participation of the patient and their support group will maximize the chances of optimal treatment. While the majority of principles of treatment are the same for the elderly population, there exist notable

TABLE 45.4 T staging for tumors of the larynx

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Supraglottis	
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis, or glottis, or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx
T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, preepiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage erosion
T4a	Moderately advanced local disease Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)
T4b	Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures
Glottis	
T1	Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility
T1a	Tumor limited to one vocal cord
T1b	Tumor involves both vocal cords
T2	Tumor extends to supraglottis and/or subglottis and/or with impaired vocal cord mobility
T3	Tumor limited to larynx with vocal cord fixation and/or invasion of paraglottic space, and/or inner cortex of the thyroid cartilage
T4a	Moderately advanced local disease Tumor invades through the outer cortex of the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Very advanced local disease Tumor invades prevertebral space, encases carotid artery or invades mediastinal structures
Subglottis	
T1	Tumor limited to the subglottis
T2	Tumor extends to vocal cord(s) with normal or impaired mobility
T3	Tumor limited to larynx with vocal cord fixation
T4a	Moderately advanced local disease Tumor invades cricoid or thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscles of the tongue, strap muscles, thyroid, or esophagus)
T4b	Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or involves mediastinal structures

differences. These differences will be discussed in each modality and for each subsite. Similar to other areas of geriatric medicine, comprehensive geriatric assessment [81, 82] is an essential part of approach to the treatment of head and neck cancer in elderly.

The three pillars of treatment in head and neck cancers are surgery, radiotherapy, and chemotherapy. Chemotherapy is the most recently adopted modality, but in recent years noteworthy evidence has made it a mainstream component of head and neck cancer treatment, especially in the form of multimodality treatments.

Surgery continues to be the standard and most established treatment for the majority of head and neck cancers. Although the principles of surgical treatment have been established for more than a hundred years, new techniques, technologies,

and concepts continue to propel the field into new frontiers. The emphasis is now on minimizing the sequela of surgery and maximizing the preservation of form and function. A few major advances have revolutionized surgical treatment of head and neck cancer. The first one is the acceptance of selective, more precise, and more limited resections based on the knowledge of the anatomy and clinical behavior of the tumor. Laser microsurgery of laryngeal tumors and transoral resection of pharyngeal tumors, without the need for mandibulotomy, and widespread use of selective neck dissection, are prominent examples. By far the most significant improvement is the introduction and subsequent refinements of free tissue transfer for reconstruction of surgical defects. This technique allows for extensive surgical resection of advanced tumors and reconstructing the resultant defect with

TABLE 45.5 T staging for tumors of the nasal cavity and paranasal sinuses

TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Maxillary sinus	
T1	Tumor limited to the maxillary sinus mucosa with no erosion or destruction of bone
T2	Tumor causing bone erosion or destruction including extension into the hard palate and/or middle nasal meatus, except extension to posterior wall of maxillary sinus and pterygoid plates
T3	Tumor invades any of the following: bone of the posterior wall of maxillary sinus, subcutaneous tissues, floor or medial wall of orbit, pterygoid fossa, and ethmoid sinuses
T4a	Moderately advanced local disease Tumor invades anterior orbital contents, skin of cheek, pterygoid plates, infratemporal fossa, cribriform plate, sphenoid or frontal sinuses
T4b	Very advanced local disease Tumor invades any of the following: orbital apex, dura, brain, middle cranial fossa, cranial nerves other than maxillary division of trigeminal nerve (V ₂), nasopharynx, or clivus
Nasal cavity and ethmoid sinus	
T1	Tumor restricted to any one subsite, with or without bony invasion
T2	Tumor invading two subsites in a single region or extending to involve an adjacent region within the nasothmoidal complex, with or without bony invasion
T3	Tumor extends to invade the medial wall or floor of the orbit, maxillary sinus, palate, or cribriform plate
T4a	Moderately advanced local disease Tumor invades any of the following: anterior orbital contents, skin of nose or cheek, minimal extension to anterior cranial fossa, pterygoid plates, sphenoid or frontal sinuses
T4b	Very advanced local disease Tumor invades any of the following: orbital apex, brain, middle cranial fossa, cranial nerves other than V ₂ , nasopharynx, or clivus

^aNote: Extraparenchymal extension is clinical or macroscopic evidence of invasion of soft tissues. Microscopic evidence alone does not constitute extraparenchymal extension for classification purposes

autologous tissue with excellent functional and cosmetic results and long term durability. More recently, robotic surgery has been explored by a few select institutions in treatment of early tonsil and oropharyngeal cancers as well as skull base tumors [83–87]. The initial results are promising; however, the eventual benefits and advantages of this technique over current standards will need further investigation.

Surgical excision also provides the clinician with the most accurate data on the pathology of the tumor, extent of invasion, and status of regional lymph nodes. It's not uncommon to upstage tumors based on the findings of the surgical specimen and final pathology report. This information is quite valuable in tailoring further courses of therapy and determining the need for adjuvant radiotherapy. Currently there are no uniform unresectability criteria; however, most surgeons consider invasion of carotid artery, base of skull, and prevertebral musculature as unresectable disease.

Assessing elderly patients for the most suitable surgical therapy continues to be a dilemma for head and neck

TABLE 45.7 N staging for all head and neck sites except the nasopharynx and thyroid

NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1*	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2*	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a	Metastasis in a single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b*	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3*	Metastasis in a lymph more than 6 cm in greatest dimension

surgeons. Many patients have other comorbidities that can affect the outcome of surgery negatively. Age, per se, is not a contraindication to surgical therapy as shown in multiple studies [88–91]. Comorbidities, on the other hand, consistently have been cited as an independent negative prognostic factor [88, 92]. The outcome of surgery is similar to younger patient groups. Furthermore, perioperative complication rate and quality of life after surgery is quite comparable with younger patients [93, 94]. A few specific areas deserve special attention. Microvascular free tissue transfer while possible and successful in elderly, requires careful assessment and selection of suitable patients. This technique can be utilized safely; however, there may be a higher complication rate and that is, again, related to accompanying comorbidities [95–97]. Time under anesthesia is another significant predictor of morbidity [88]. This factor has to be considered when recommending procedures that involve free tissue transfer, since this technique adds a significant time to the duration of operation. A number of procedures, such as supraglottic laryngectomy are generally tolerated worse in elderly due to increased risk of aspiration. It's advisable to avoid such procedures or carefully assess the candidate's biologic age and status to assure desirable outcome [98].

Radiotherapy is used as the primary treatment for tumors of nasopharynx, early stage glottic larynx, tonsil, and base of tongue, as well as adjuvant therapy for most other head and neck cancers in advanced stages. Postoperative radiation has been shown to improve local control and survival better than surgery alone [99]. New techniques and concepts such as "Intensity Modulated Radiation Therapy" (IMRT), hyperfractionation, and accelerated fractionation have brought better efficacy and less toxicity.

Advanced tumors are commonly treated with multimodal therapy consisting of surgery and adjuvant radiotherapy. The advantages of radiotherapy in a postoperative setting are reduced wound complications, reduction in target tumor volume, and clear definition of the extent of tumor. Adjuvant radiotherapy should be considered in all locally advanced cancers and also in patients with early cancers with sinister pathologic features. These features are listed in Table 45.12 [100].

There are multiple methods and techniques to deliver ionizing energy to the tissues. In general, the methods are divided into teletherapy (external beam radiation) and brachytherapy. In teletherapy, the source of ionizing beam is away from the patient. The energy can be in the form of ionizing rays such as photons, X-rays, or gamma rays; or in the form of high energy particles such as electrons, neutrons, or proton beams. In brachytherapy the source of radiation is implanted in the patient. Each technique has its own advantages and applications. Electron beams are superficially penetrating and are used as a boost to superficial areas (e.g., posterior neck nodes). On the other hand, photon beam radiation spares the skin relatively and affects the deeper tissues

TABLE 45.12 Indications for postoperative radiotherapy

Primary tumor features

Advanced T stage (bulky tumor; involvement of bone, nerves, skin)
 High histologic grade
 Positive surgical margins
 Lymphovascular invasion
 Perineural spread

Lymphatic spread features

Involvement of more than two nodes
 Involvement of more than one level of the neck
 Lymph node >3 cm (N2, N3 disease)
 Extracapsular spread
 Microscopic or gross residual disease in the neck
 Involvement of critical level of neck nodes (Levels IV and V)

more specifically. For lesions of nasopharynx, oral cavity, and oropharynx, brachytherapy in form of radioisotope implants (Iodine, Iridium, Radium, or Gold) can be quite useful. The methods of delivery have undergone significant improvement in the past few decades. For IMRT, a computer-controlled machine is used to produce a three-dimensional model in which many radiation beams are used to optimize the dose in the target area, while sparing normal tissues. More recently tomotherapy, which integrates CT or PET-CT technology into a linear accelerator, has been introduced and is being used more frequently. Cyberknife or stereotactic radiosurgery is another new development that is currently being explored for head and neck cancers. These methods, although quite exciting, have not been validated in prospective controlled trials yet [101, 102].

The typical radiotherapy regimen for head and neck cancers consists of daily fractions of 1.8 c–2.0 cGy, 5 days a week to a maximum dose of 70 Gy over 7 weeks. For most adjuvant treatments a total dose of 60–66 Gy is administered. When extracapsular extension is present, increasing the dose to 63 Gy improves locoregional control [103]. The toxicity of radiation escalates exponentially and becomes quite significant, especially in doses above 70 Gy.

In general, it is preferable to start postoperative radiotherapy within 6 weeks after surgery. Long term delays or interruptions in treatment are not desirable, theoretically due to repopulation of cancer cells. Cancer cells in general cannot repair the radiation damage as fast as normal tissue. In order to take advantage of this phenomenon, two techniques have been introduced: hyperfractionation and accelerated fractionation. In hyperfractionation, two to three reduced dose fractions are delivered every day (1.1–1.25 Gy/fraction). This method achieves a higher total dose without increasing the chronic toxic effects of a standard dose. Accelerated fractionation uses fractions of 1.6–1.8 Gy more than once a day and the goal is to achieve 10 Gy per week in a reduced time

compared to standard fractionation. So far most studies have shown modest improvement in locoregional control and marginal improvement in survival [104, 105]. The combination of altered fractionation and chemotherapy has been more promising [106–108].

Radiotherapy has been used extensively in treatment and palliation of elderly head and neck cancer patients. Strong evidence supports both safety and efficacy of this modality and clearly shows that age is not a limiting factor in utilization of radiotherapy [109–111]. Radiotherapy in general has similar efficacy and side effect profile in elderly patients and general population [112, 113]. It has even been used successfully in patients older than 90 years old [114]. Although traditionally elderly patients have been treated with lower doses of radiation, there is no evidence that this is necessary. All studies have shown that elderly patients can tolerate and benefit from the standard regimens of radiation without increased morbidity and mortality. Newer modalities of radiotherapy such as altered fractionation and IMRT has been used in elderly patients. Since these modalities have been introduced more recently specific data on elderly population is scant. There is suggestion of reduced benefit of hyperfractionation in elderly patients and those with poor performance status [115]. IMRT is also used widely in treatment of different head and neck cancers, but more evidence needs to be acquired to determine if there are differences in treatment and complication profiles of this technique in elderly patients. In general early and late toxicities of radiotherapy occur with similar frequency in elderly and general population. The management of toxicities such as xerostomia and mucositis is the same as in younger patients. Elderly patients might need to be monitored more carefully during the treatment, since they are more susceptible to loss of fluids and electrolytes [116].

Chemotherapy has evolved quite significantly in recent history from a palliative option to a central component of treatment of locally advanced tumors. Cisplatin is considered a standard agent in combination with radiation and other agents. Carboplatin, the other platinum agent, is less toxic, but also less active against squamous cell cancers. They both are comparable radiosensitizing agents. Taxane-based agents are quite active and have been used in induction regimens for locally advanced tumors. One of the more significant advances is the use of EGFR inhibitors. Cetuximab is the first agent that has successfully been used in treating head and neck cancers [67, 117]. Other novel therapies that are being investigated include monoclonal antibodies or multi-selective tyrosine kinase inhibitors against EGFR or other dysregulated pathways in head and neck cancer, and antiangiogenesis agents. The combination of these novel therapies with chemotherapy and radiation is actively being pursued. At present time there is no specific data in use of cetuximab in elderly patients; however, ongoing studies at this time are recruiting elderly patients.

Only about one-third of patients with head and neck cancer will present in early stages (I and II). In early stage disease, the tendency is to use one modality that offers the best chance for cure and minimizes morbidity. The preferred method of treatment in oral cavity cancers is surgery for the primary tumor with elective neck dissection based on the probability of lymph node metastases [118]. This method offers the best functional outcome and most accurate staging. It also avoids the late toxic effects of radiotherapy. In addition, in case of recurrence, radiotherapy can be used as a salvage option. For early stage laryngeal tumors, either organ preserving surgery or radiotherapy are acceptable and will produce comparable functional results and cure rates [119–121]. The choice depends on tumor location, local expertise, and patient's preferences. For early laryngeal lesions, laser excision is the preferred modality. In early-stage tumors of the oropharynx and hypopharynx, radiotherapy is usually recommended as the first choice. It produces similar cure rates to surgery with less morbidity [122, 123].

Treatment of locally advanced disease uses a multimodality approach based on surgery, radiation and chemotherapy. One of the major advances of treating this category is the introduction of chemoradiotherapy, which concurrently uses chemotherapy and radiation. Many trials have shown the superiority of chemoradiotherapy in comparison to radiotherapy alone with regard to locoregional control, disease free survival, and in some studies overall survival [124, 125]. In postoperative settings adding chemotherapy to radiation showed benefit, especially in the presence of extracapsular spread or positive margins [126]. In general, the same principles are used for advanced disease with the addition of chemoradiation or radiation to surgery. In oral cavity cancers, advanced tumors are treated with surgery followed by radiation or chemoradiation. Advanced oropharyngeal tumors are treated with primary chemoradiation that offers good efficacy and functional results. In cases of advanced laryngeal cancer, many experts still advocate primary surgery, since preserving an already dysfunctional organ does not add much to the quality of life and the failure rate of chemoradiotherapy is high in these situations.

Management of the neck is an integral part of the treatment of advanced head and neck cancers. Patients exhibiting positive margins, multiple positive nodes, or extranodal spread are generally considered candidates for postoperative chemoradiotherapy. However, use of this aggressive adjuvant therapy needs to be balanced against possible complications such as severe mucositis, neutropenia, and pharyngeal stricture.

The standard chemotherapy regimen is platinum based. Cetuximab plus radiation has been successfully used and should be strongly considered in patients who cannot tolerate standard chemotherapy. Induction chemotherapy has the potential to reduce the incidence of distant metastases.

Although platinum based regimens produce high response rates initially and result in good locoregional control, most of the trials have failed to show any survival benefit [127]. Introduction of taxane-based agents has improved survival or organ preservation [128–130]. Concurrent chemotherapy has been shown in a series of meta-analyses to be the most effective method and has the potential of becoming the standard of care. The most recent data indicates a 6.5% survival benefit at 5 years with this method [3].

Unlike radiation, which is fairly well tolerated and there is overwhelming evidence in its benefits in elderly population, not enough data exists for chemotherapy regimens. In addition, quite a few studies have shown higher complication and toxicity rate in elderly populations [131]. The benefits of chemotherapy also seem to be more pronounced in younger patients. This preliminary evidence should not discourage practitioners in considering elderly patients for chemotherapy. Certain elderly patients can benefit from these new regimens by careful assessment and attention to overall status of the patient and the disease.

Unknown Primary Tumors

A solitary lateral neck mass in adults is always suspicious for malignancy. Primary malignancies of the neck are extremely rare and these masses are most commonly a metastatic lymph node. If the source of malignancy is not found after a thorough history, physical exam, endoscopy and imaging, then it is classified as an “unknown primary tumor”. The most common sites for lymph node involvement are upper jugular lymph nodes (level II) (Fig. 45.6) followed by middle and lower jugular nodes (level III and IV). The location of lymphadenopathy usually correlates with the origin of the tumor. In

FIGURE 45.6 Right neck mass. Metastatic cutaneous squamous cell carcinoma to level II (upper jugular) lymph nodes. Primary source was unknown at the time of presentation.

general, two-thirds of all primaries arise from supraclavicular sources. These primaries are located in nasopharynx and oropharynx in one-third of cases; tonsil and base of tongue in another third, and the rest come from different locations. A few can arise in the hypopharynx. Most metastases from infraclavicular sources (two-thirds of cases) will involve supraclavicular lymph nodes (level IV). Generally, 50% of the primaries are found in the lungs. Breasts, stomach, pancreas, and ovaries contribute to the rest of cases.

The clinician who encounters a patient with an isolated neck mass should resist the temptation to perform an excisional biopsy as a first step. Multiple studies have shown that such an intervention will increase the incidence of wound complications, local recurrences, and distant metastases [132–135]. The approach should be systematic and stepwise, preferably by a practitioner well versed in management of head and neck cancers and capable of performing different diagnostic and therapeutic procedures that might be required in the course of work-up and treatment. The first step is a thorough history and physical exam including nasopharyngoscopy and fiberoptic laryngoscopy. FNA of the suspicious lymph node should be the next step. If FNA results confirm malignancy or is suspicious then further work-up is necessary. Even if the results are inconclusive or benign, in high risk patients it is advisable to proceed with a thorough work-up. Imaging, preferably by CT and MRI, are necessary to find the possible primary and better delineate the extent of disease in the neck. T2 weighted MRI images are superior in characterizing submucosal lesions [136]. EBV antibody titers may be helpful in directing a diagnosis toward nasopharyngeal primaries. Examination under anesthesia is the next step. A panendoscopy should be performed to inspect the nasopharynx, larynx, pharynx, esophagus, and lungs very carefully. While blind biopsies do not offer high yield, directed biopsies of suspicious areas in endoscopy can be quite helpful. Directed biopsies should be based on the findings of the endoscopy, the patterns of lymphatic spread and the location of the metastatic lymph nodes. Some references have advocated ipsilateral tonsillectomy at the time of panendoscopy, especially if the involved lymph node is at level II (upper jugular) [137].

If after all these interventions a source is still not found or the FNA findings are highly suspicious for lymphoma, then performing an open biopsy is prudent. Before attempting the biopsy, the patient should be informed of the possible need for a formal neck dissection based on intraoperative findings. If the practitioner or the patient would rather wait for the permanent pathology specimen, it is extremely important to plan the incision in a way that can be excised if a definitive operation becomes necessary.

The standard treatment for metastatic squamous cell carcinoma of the neck with an unknown primary is neck dissection plus postoperative radiotherapy. Patients with N1 and

extracapsular spread, or N2 and N3 disease will benefit the most from postoperative radiation to the neck. In cases of N1 disease without extracapsular spread there are different opinions. Some advocate surgery alone, some recommend excision of the node only with postoperative radiation and others press for neck dissection plus postoperative radiation. The practice and extent of prophylactic radiotherapy is a matter of controversy [138]. Irradiation of the involved side of the neck plus the contralateral side, nasopharynx, ipsilateral tonsil, and base of tongue has been advocated. The benefit of this approach been questioned and several adverse effects have been raised. Prophylactic radiation can induce later mucosal tumors. It causes significant morbidity in the form of xerostomia, dysphagia, and dental problems. Lastly, if the primary tumor is an excised skin cancer, or from an infraclavicular source, the patient will not benefit from radiation. In cases of positive EBV antibody it is recommended to include the nasopharynx in the radiation field. The rate of manifestation of primary tumors post radiation is 4–16%, which is the same as the rate of second primaries.

In general, patients with unknown primaries should be under close surveillance after treatment whether or not they receive postoperative radiation. Recurrence rates after treatment range from 11 to 14% for mucosal malignancies. The prognosis of recurrence is dependent on pathologic features of the tumor such as grade and presence of extracapsular spread. Patients whose primary tumor was never found have the best prognosis.

In cases of adenocarcinoma metastatic to the cervical lymph nodes, the majority of patients have other areas of distal metastases and the overall outcome is not dependent on the treatment of the neck. The primary tumor is usually infraclavicular and occasionally can be found in salivary glands [139]. Metastatic adenocarcinoma in the upper part of the neck is generally from the major or minor salivary glands and is commonly considered a surgical problem, while metastatic adenocarcinoma in the lower part of the neck is most likely from the lung or abdominal organs and considered to be a systemic disease and not a surgical problem.

Treatment of the Neck

Cervical lymph nodes are the most common site of metastases from head and neck cancers. Adequate and effective treatment of the neck is of utmost importance in management of head and neck cancer patients. The principles of treatment have been established for more than 100 years now and continue to evolve. Cervical lymphadenectomy was introduced by Butlin and was expanded to radical neck dissection by Crile. This operation was subsequently popularized by Hayes Martin. Radical neck dissection, although an

effective cancer operation, carried a significant burden of morbidity. In this operation, all the lymphatic tissues of the neck from level I to level V are removed in addition to the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. A long list of morbidities accompanied this operation. The most significant is “shoulder syndrome” due to sacrifice of the spinal accessory nerve. A detailed list can be found in Table 45.13. Suarez from Argentina and later Bocca from Italy introduced the concept of functional neck dissection which was subsequently transformed to modified radical neck dissection. In this modification, the structures that were not directly involved with cancer were spared. Many studies have shown that the efficacy of RND and MRND are comparable and they both offer equivalent oncologic results. MRND, especially when all three structures are preserved, is a much less morbid operation than RND. Later, based on works by Lindberg and then Shah, the patterns of

TABLE 45.13 Complications of radical neck dissection

Timing and nature of complication	Sequelae
<i>Intraoperative</i>	
Injury to nerves	
Marginal mandibular nerve	Deformity of angle of mouth
Hypoglossal nerve	Difficulty in moving the tongue
Vagus nerve	Hoarseness, aspiration
Sympathetic chain	Horner's syndrome
Phrenic nerve	Paralyzed ipsilateral diaphragm
Brachial plexus	Weakness or paralysis of limb muscles
Injury to thoracic or major lymphatic duct	Chyle leak
Injury to dome of pleura	Pneumothorax (tension)
Injury to pharynx or esophagus	Salivary fistula
<i>Other complications</i>	
Stimulation of carotid bulb	Bradycardia
Injury to internal carotid artery	Stroke
Air embolism through major venous injury	Hypotension, death
<i>Early and Intermediate postoperative</i>	
Reactionary or secondary hemorrhage	Hematoma
Carotid artery exposure and rupture	Stroke, Death
<i>Physiologic consequences</i>	
Spinal accessory nerve	Shoulder dysfunction
Other nerves	Anesthesia of skin flaps, ear lobe, and cheek
Internal jugular vein ligation (bilateral)	Cerebral edema, airway obstruction, blindness, edema of face and neck

Source: Robbins KT et al (2002) Neck dissection classification update: revisions proposed by the American Head and Neck Society and the American Academy of Otolaryngology-Head and Neck Surgery. Arch Otolaryngol Head Neck Surg 128(7): 751–758

lymphatic spread for different sites of head and neck cancers were defined. This knowledge led to the introduction of selective node dissection in which only the nodal groups at highest risk of metastases are removed, which spares the patient from the morbidity associated with comprehensive neck dissection. All of these modifications caused significant cluttering of the nomenclature. In an effort to standardize the vocabulary, the American Academy of Otolaryngology-Head and Neck Surgery convened a special task force in 1991. This task force published a report for standardizing different variations of neck dissection. The report was then updated in 2002. Currently, most head and neck surgeons use this classification when addressing the different variations of neck dissection. The 1991 and 2001 classifications are compared in Table 45.14.

In general, cervical lymph nodes are addressed in three different settings. First is management of the neck in clinically N0 disease, where there is no evidence of metastases in clinical examination and imaging. There is still controversy on the necessity and extent of dissection. A few guidelines are generally accepted. The need for elective neck dissection is justified if the probability of occult metastases is about 15–20%. The neck can be addressed either by radiotherapy or by neck dissection, but the tendency is to perform selective neck dissection. This will minimize the morbidity and avoid long term consequences of radiation. When the risk of metastases is less than 15%, it is not justified to subject the other 85% without disease to treatment. An exception is when addressing the primary tumor will require access through the neck. In these cases, selective neck dissection can be added to the procedure without significantly increasing the morbidity.

In terms of the extent of lymphadenectomy in elective neck dissection, there is now good evidence to guide clinicians. This evidence is mostly based on works of Shah et al., who established the patterns of lymphatic spread in head and neck cancers. Based on his work and other investigators such

as Byers et al., selective node dissection is widely accepted as adequate treatment in elective neck dissection. In general, for tumors of the oral cavity, dissection of levels I–III is performed. Levels II through IV are dissected in oropharyngeal tumors; however, quite often surgical access requires dissection of level I nodes and in this case levels I–IV are dissected. For hypopharynx and laryngeal tumors, levels II through IV are removed.

If there is evidence of disease in the neck, the traditional treatment was to perform radical neck dissection. Interestingly, even in presence of clinical evidence for lymph node metastases, disease will be found in approximately 80–85% of specimens. Nowadays, based on many prior studies, the tendency is to preserve the organs that are not directly involved with the disease. There are studies that show preservation of the spinal accessory nerve or jugular vein will not jeopardize the efficacy of the operation. Based on this evidence, it is generally accepted that modified radical neck dissection is equivalent to radical neck dissection as long as the preserved organs are not directly involved with the tumor. The next leap of faith was applying the principles of selective neck dissection to the node positive patient. There is quite a bit of controversy on this topic. An important principle is to treat the neck with radiation after neck dissection in all cases of node positive disease, except for a few special cases. Postoperative radiation improves local control from 30 to 50% for surgery alone to 70% even in cases of N2 and N3 disease. There are quite a few studies demonstrating that selective node dissection can be comparable to modified radical neck dissection as long as postoperative radiotherapy is used. While it can be said that the standard is still to perform modified radical neck dissection for node positive disease, there is an ever growing application of selective neck dissection in this group. The levels of dissection are as described for elective neck dissection. If there is evidence of disease in the specimen, the majority of practitioners will recommend postoperative adjuvant radiotherapy. In the N3 neck and when the extent of disease is beyond the first and second echelon of nodal drainage, the tendency is to perform comprehensive neck dissection and adjuvant radiotherapy, instead of selective neck dissection.

The last application of neck dissection is planned neck dissection or in cases of recurrence after definitive chemoradiation. Performing neck dissection is fraught with complications in this setting. There are not that many studies that provide evidence as to the effectiveness of the operation. In general, it is recommended to perform planned neck dissection in N2 and N3 disease after chemoradiation regardless of evidence of residual disease. However this approach was recently modified with the routine use of PET scans in the follow-up of patients receiving chemoRT. Patients with PET negative results are generally observed. In cases of N1 disease where there is no evidence of disease, most will observe the patient.

As to the extent of operation, most agree on comprehensive neck dissection with preservation of the spinal accessory nerve if possible. With widespread use of PET scans and other biologic studies and markers, these recommendations will probably change and more tailored approaches based on the biology of the tumor will be adopted.

The use of radiotherapy to address disease in the neck is quite established now. Radiotherapy can be used alone in treating disease in the neck. A dose of 60 Gy results in sterilization of 90% of pathologically involved nodes that are less than 2 cm. As the disease bulk increases, it takes higher doses of radiation to control the disease and at the same time, the rate of control decreases. For nodes larger than 3 cm, doses of 70 Gy can achieve control in approximately 80% of cases. Except for nasopharyngeal and tonsillar cancers that are very radiosensitive, nodes significantly larger than 3 cm rarely disappear with radiation alone. Based on these facts, N2 and N3 disease are treated with a combination of surgery and radiation. In preoperative settings, doses of 50–60 Gy are administered to the involved node. In postoperative settings, the dose is around 66 Gy. Another important factor is to avoid delay between therapies. On average, it is desirable to proceed with the next modality in 4–6 weeks. Further delays might cause repopulation of cancer cells and also increases morbidity.

Nasal Cavity and Paranasal Sinuses

Tumors arising from the paranasal sinuses are rare. They only comprise 3% of head and neck cancers. The most common malignant tumor is squamous cell carcinoma (80%) followed by adenoid cystic carcinoma and adenocarcinoma (10%), and numerous other tumors such as neuroendocrine tumors, malignant melanoma, sarcomas, and hematopoietic and lymphatic tumors. The most common site for squamous cell carcinoma is the maxillary sinus followed by the ethmoid sinus. Most symptoms are quite similar to benign processes of the sinuses (nasal obstruction, rhinorrhea, and congestion) and therefore most are diagnosed later in their course. Advanced symptoms include facial pain, diplopia, proptosis, or symptoms of intracranial invasion like headache, neuropathies, and frontal lobe syndrome. CT scanning and especially MRI are preferred imaging methods.

Since most tumors are found in advanced stages, treatment usually includes surgery and radiation. Depending on the size and location of tumor, different surgical techniques are used. External ethmoidectomy is the most limited operation and is used for benign tumors of the ethmoid region or biopsy of sphenoidal region tumors. For small tumors of the lateral nasal wall, medial maxillectomy through a lateral rhinotomy approach is the procedure of choice. Partial

maxillectomy can be used in treating infrastructure maxillary tumors. This operation is technically easier and cosmetic results are quite good. Local control with this approach is quite acceptable. Suprastructure lesions on the other hand are more challenging. They usually require total maxillectomy with reconstruction of the orbital floor. Orbital exenteration might become necessary depending on the extent of orbital invasion by tumor. The most extensive surgeries require craniofacial resection with an intracranial approach by a neurosurgeon and facial approach by a head and neck surgeon for tumors that involve the base of the skull. Endoscopic approaches have become quite popular recently and a few select centers resect malignant tumors by this technique. This approach, however, is mainly used for benign and intermediate tumors [140]. More recently reports of using surgical robots in skull base tumors in preclinical stages have emerged [83]. Appropriate rehabilitation after surgery is very important in this group of patients. This goal is achieved by involvement of a prosthodontist for smaller defects and use of microvascular free tissue transfers for larger and more complex ones. Small defects usually can be covered with a split thickness skin graft and then a temporary prosthesis placed in the defect. After the defect has stabilized a final prosthesis is fashioned.

Most cases will require adjuvant radiotherapy. The delivery of radiation is more complicated because of the proximity of the brain, spinal cord, and orbit. The complication profile of radiotherapy has been reduced by the advent of IMRT techniques, which reduces the dose to sensitive and noninvolved organs [141]. The 5-year survival rate of maxillary tumors treated with surgery and radiation is 46–67% [141–143]. Cervical lymph node metastasis occurs in approximately 15–25% of cases and is usually a bad prognostic feature [144]. More recently, reports of chemoradiotherapy have shown more promise in controlling these tumors. A report from Japan has shown impressive results with use of radiation and concurrent arterial infusion of 5-FU, tumor reduction surgery, and immunotherapy. They improved 5-year survival by more than 20% from 20 to 54% [145]. Other reports also have shown benefit by using concurrent cisplatin and split course radiotherapy in advanced cases [146].

Adenocarcinomas harbor equally poor outcome (5 year survival of only 20% in poorly differentiated tumors). They are more common in professions related to woodworking, furniture making, and leather-work [147]. They are quite aggressive locally and the best chance is en bloc resection if possible. Adenoid cystic carcinomas have a favorable 5-year survival of 75% but the 15-year survival declines to 20% [148]. These tumors can spread along nerve sheath structures and have a tendency toward distant metastases rather than regional metastases [148]. In spite of this fact, the most common cause of death is invasion of the skull base. Treatment is surgical with added adjuvant radiation if margins are suspicious.

Nasopharynx

Nasopharyngeal carcinoma (NPC) is a relatively rare disease outside parts of southern China, Hong Kong, and Singapore. It is more common in the Chinese population of these areas and the risk of cancer goes down with emigration, but is still much higher than other ethnicities [149]. It is more common in men than women (2.5:1). A multifactorial pathogenesis has been proposed based on patterns of distribution. Genetic susceptibility, latent EBV infection, dietary habits, and smoking are all well known factors. EBV infection plays a crucial role in progression to severe dysplasia. Diets high in preserved food, salted fish and deficient in carotene, fresh fruit and fiber have also been implicated [150].

The World Health Organization (WHO) has divided NPC into three subtypes [151]. WHO type I is keratinizing squamous cell carcinoma. This subtype is relatively more common among cases in the US (20–30%), but is rare in Asia (1–3%). WHO type II is non-keratinizing carcinoma. WHO type III is undifferentiated carcinoma or lymphoepithelioma. Types II and III are more radiosensitive and achieve better local control but have higher rates of distant metastases [152, 153].

NPC patients are relatively younger than the rest of head and neck cancer patients. Incidence starts to increase in second decade of life and peaks in fourth and fifth decade. The most common presenting symptom is cervical lymphadenopathy. Lymphadenopathy starts at the jugulodigastric nodes (level II) and continues to progress downward to levels III and IV. Other symptoms include nasal obstruction, epistaxis, otitis media, and referred pain to the ears. Multiple cranial nerve palsy can be seen (cranial nerves VI, IV, and V, and in case of extension to jugular foramen cranial nerves IX, X, and XI). Five percent of patients will present with distant metastases, most commonly to bones followed by the lungs and liver [154].

Diagnostic work-up includes a detailed history and physical including nasopharyngoscopy. The most common sites of origin are the Rosenmuller fossa and nasopharyngeal roof. Biopsies should be taken for histologies. If biopsy of a cervical lymph node is required, FNA is the preferred method and open biopsies should be avoided. EBV DNA titers have prognostic value and should be checked. In case of suspicious disease, high titers of EBV antibody are very sensitive and specific. Liver function tests may be helpful in ruling out liver metastases. The preferred imaging modality is MRI, which provides excellent soft tissue details. A chest X-ray should be obtained to rule out metastases. Staging is based on the sixth edition of AJCC-UICC TNM system and is detailed in Tables 45.3, 45.8 and 45.11.

The primary treatment for nasopharyngeal cancer is radiotherapy. NPC is extremely radiosensitive and even bulky lymphadenopathy responds well to radiotherapy. In addition,

these tumors are difficult to access surgically and the morbidity of surgery can be quite high. External beam radiation is the most commonly used method, although there is a role for brachytherapy in selected cases when the disease volume is not very large. Fields of radiation include the primary tumor, retropharyngeal nodes, and bilateral neck and supraclavicular nodes. Doses of 70–76 Gy are administered to the diseased areas. Prophylactic doses of 50–60 Gy are administered to at risk areas in the neck. With the advent of new radiotherapy techniques such as three-dimensional conformal, IMRT, and altered fractionation, the morbidity of treatment is reduced, and the incidence of “geographic miss” is lower. Radiation boost in the form of brachytherapy can be used in T1 and T2 lesions to improve local control. Overall survival for use of radiation therapy alone is in the range of 50–76%. Results are excellent in early stage disease. For locally advanced disease, addition of chemotherapy in the forms of induction, concurrent and adjuvant chemotherapy has added improved survival and local control rates. The two most commonly used drugs are cisplatin and 5-FU. The role of surgery is limited to treating residual or recurrent disease. Neck dissection after radiotherapy for residual disease can be performed. In cases of brachytherapy, the surgeon can play a role in inserting brachytherapy catheters.

Recurrent disease can be treated with radiotherapy or surgical excision. If detected early, there is a potential for control and these patients need to be treated aggressively. Follow-up of the patients should include careful physical exam, radiologic imaging, and laboratory tests to monitor potential treatment-related side effects including pituitary dysfunction should be considered.

Oral Cavity

Oral cavity cancers have the chance of being detected relatively earlier than other head and neck cancers. However, common manifestations with benign oral disease make delays in diagnosis quite possible as well. Oral cavity cancers, including lip cancers, account for about 13% of head and neck cancers [155]. It is slightly more common in men. A majority of cases are squamous cell carcinoma with adenocarcinoma, verrucous carcinoma, lymphoma, and Kaposi’s sarcoma constituting the rest.

The most common presenting symptom is a nonhealing ulcer (Fig. 45.7). The most common sites are the tongue and floor of the mouth. The most recent staging is described in Tables 45.2 and 45.10. The treatment plan is based on the location, stage, relation to the mandible, and incidence of occult or gross nodal metastases. Early stage lesions can be treated effectively with one modality (surgery or radiation). More advanced lesions usually require a combination of different modalities.

FIGURE 45.7 (a) Early tongue cancer (b) Advanced tongue cancer presenting as nonhealing ulcer. Note poor dental hygiene.

Most lip lesions occur in the lower lip and men are afflicted more commonly than women. Most malignancies of the lower lip are squamous cell carcinomas, while the upper lip harbors more basal cell carcinomas. Risk factors include prolonged sun exposure, fair skin complexion, immunosuppression, and tobacco abuse.

Choice of treatment depends on the size and location of the tumor. For small lesions, V-shaped resection with primary closure or a local flap is quite adequate. Excision of lesions up to one-third of lip length by this method results in acceptable functional and cosmetic outcome. For lesions between one-third and two-thirds of lip length usually involve a lip switch flap (Abbe-Estlander). For larger lesions and those which involve the commissure, options are a Gillies fan flap, bilateral advancement flap, and Karapandzic flap or radial forearm free flap [156]. Surgical excision can cause microstomia and oral incompetence, which are more common after removal of large lesions. Cervical metastases are rare (10%) and prophylactic neck dissection is not recommended. In cases of clinically positive lymph nodes, therapeutic neck dissection is indicated. Positive margins, perineural invasion, and positive cervical nodes, among others, are indications for adjuvant radiotherapy. Five-year survival for T1 and T2 lesions is excellent (90%). For larger lesions (T3 and T4) survival is decreased to 75%. Presence of cervical metastases lowers survival to almost 50%.

Cancers of the oral tongue are more common on the posterolateral aspect (75%) than on the anterolateral and ventral surfaces (20%). These tumors arise in the epithelium and invade deeper tissues. Patterns of invasion can be varied. The tumor can spread to the midline and contralateral side, posteriorly to base of the tongue or inferiorly to the floor of the mouth. In extreme cases they can involve the mandible. Perineural invasion can happen and will cause numbness, fasciculation, and atrophy of the tongue. Most lesions (75%) are diagnosed in an early stage (T1, T2). Partial glossectomy with negative margins provides good oncologic and functional

results. Resection of one-fourth to one-third of the oral tongue can be tolerated quite well with minimal adverse functional effects. The defect can be left open to heal with secondary intention or covered with a split thickness skin graft. If excision of the tumor requires removal of half of the tongue, the best strategy is to repair the defect with a fasciocutaneous free flap (radial forearm or anterolateral thigh). If a significant portion of the floor of the mouth are to be removed, again free flap reconstruction provides the best outcome. Tongue tumors are distinct in that depth of invasion is a better predictor of presence of cervical node metastases than T stage [78]. Based on a meta-analysis of multiple studies, for tumors with depth of invasion more than 4 mm, prophylactic neck dissection is recommended, since the probability of neck metastases is around 16%. Another phenomenon is the possibility of skip metastases. Tongue lesions can skip level I and II neck nodes and present in levels III and IV in almost 16% of cases. Based on this observation, some authorities advocate removal of neck nodes from level I to IV instead of performing a supraomohyoid neck dissection (level I–III) [157]. Lesions close to the midline may require bilateral neck dissection. Advanced lesions (III or IV) and those with positive or close surgical margins, neck nodes metastases will require adjuvant radiation which will improve locoregional control. The 5-year survival for early stage tumors is 75% and for advanced cancers (III and IV) is almost 50%.

Floor of mouth lesions are more common in men and usually present in the sixth decade of life. For small lesions, transoral excision is adequate and provides excellent results. The defect can be left open to be closed by secondary intention or with a split thickness skin graft. For larger lesions, immediate reconstruction with a free flap or local flaps is usually necessary. If the lesion is close to submandibular salivary glands, excision of the gland becomes necessary in a majority of cases. More extensive lesions may require different forms of mandibulectomy. Cervical metastases are common and can be found in up to 50% of cases. Lesions in the

anterior floor of the mouth can metastasize bilaterally. Submandibular lymph nodes are most commonly affected. Survival for floor of mouth cancers are 90% for stage I disease, 80% for stage II, 65% for stage III, and 30% for stage IV [158, 159].

Buccal lesions are most common in users of smokeless tobacco and are usually located in the region of the third mandibular molar. Surgery and radiation have equal success in treating these cancers. However, surgery is preferred for most lesions since the rate of complications is lower. Primary radiotherapy is considered for patients who are not appropriate candidates for surgery and immediate reconstruction. Small lesions can be excised transorally. Larger lesions with involvement of the oral commissure, full thickness of cheek, skin or mandible will require composite resection and immediate reconstruction with free flap tissue transfer. For advanced lesions adjuvant radiation therapy is indicated. The incidence of lymph node metastases is relatively low and neck dissection is reserved for advanced cases or clinically positive nodes. Five-year survival is around 75% for stage I, 65% for stage II, 30–60% for stage III, and 20–50% for stage IV [160, 161].

Alveolar ridge tumors are relatively uncommon and account for approximately 10% of oral cavity cancers. Mandibular lesions are more common than maxillary gingival tumors. Close proximity to bone makes osseous invasion more common in these tumors. Management of the mandible will be discussed in detail later. Overall incidence of lymph node metastases is quite high (25%). This fact makes prophylactic and therapeutic neck dissection much more common in management of alveolar ridge tumors. Treatment is surgical excision and, in advanced tumors, adjuvant radiotherapy. Primary radiotherapy is not recommended in tumors with bony invasion. For early stage disease the 5-year survival is as good as 85%. In patients with metastatic spread, survival ranges from 35 to 59% [162, 163].

Retromolar trigone tumors usually present in advanced stages. Mandible involvement is common and invasion of the tonsillar fossa, faucial arch, and base of tongue happen often. Surgical treatment followed by radiation is the preferred method of treatment. Because of proximity to bone, surgical excision usually involves marginal or segmental mandibulectomy for more advanced tumors. Most of these tumors have metastasized to neck nodes at diagnosis and neck dissection is commonly performed at the time of surgical therapy. Survival ranges from 76% for T1 to 54% for T4 lesions at 5 years. Patients without nodal involvement have an overall survival of 69%. This rate falls down to 56% for N1 and 26% for N2 disease. Patients who have undergone surgery and adjuvant radiotherapy have better survival than primary radiation (44% vs. 23%) [164].

Hard palate tumors are mostly squamous cell carcinoma; however minor salivary gland tumors, mucosal melanoma

and Kaposi's sarcoma can occur in this location. Treatment is mainly surgical and depends on the stage and extent of tumor requiring different degrees of maxillectomy (infrastructure in earlier lesion and total maxillectomy for more advanced tumors). The rate of metastases is low and prophylactic neck dissection is not routinely performed. The 5-year survival is reported from 40 to 60% [165, 166].

Oropharynx

The most common sites are the tonsil and base of tongue for cancers of oropharynx. Cancers of the soft palate and pharyngeal wall do occur, but are less common. Oropharyngeal cancers are on the rise especially in non-smokers and younger men. In general these tumors tend to be diagnosed late and there is a high incidence of lymphatic spread at the time of diagnosis. Radiation is used as primary treatment for oropharyngeal cancers much more commonly than oral cavity tumors due to the high morbidity of surgical excision in this region. Similar to oral cavity, advanced tumors require a combination of surgical and radiation therapies.

Tonsils are the most common site and account for almost 75% of oropharyngeal cancers. Most early cancers are asymptomatic. It is not uncommon to find cervical lymphadenopathy as the presenting symptom of tonsillar cancer (Fig. 45.8). The incidence of positive lymph nodes at presentation is as high as 40–76% in different reports. The most common site of lymph node metastases is level II nodes; however, retropharyngeal and parapharyngeal nodes can also

FIGURE 45.8 CT scan of neck. Metastatic tonsillar cancer to left level II lymph node. Note cystic appearance of lymph node. This is one of the characteristic features of tonsillar metastases and can be mistaken with bronchial cleft cyst.

be afflicted. These tumors tend to invade the base of tongue in most advanced cases. For early tonsillar tumors, surgery and radiation yield equal results. Surgical treatment is composed of radical tonsillectomy plus neck dissection. In current practice, majority of cases are treated with radiation primarily. Radiation fields include the primary site and ipsilateral neck, including retropharyngeal nodes. It is important to spare the contralateral parotid gland to reduce the complication of xerostomia. Radiation alone results in local control of 70–90%. Salvage surgery is also successful in two-thirds of patients. This combination results in ultimate local control of 90% in early stages. In advanced lesions (T3–T4), the combination of surgery and radiotherapy is standard practice. Resection of large lesions through the mouth is difficult and many patients will require a lower lip splitting incision with mandibulotomy. More recently, interest in using a surgical robot to resect these tumors without mandibulotomy has arisen in multiple centers [167, 168]. Comprehensive neck dissection is an integral part of surgery. Adjuvant radiation improves local control quite significantly. Surgery plus adjuvant radiation results in overall 5-year survival of 75% versus 48% for surgery alone [169, 170]. T-stage specific survival of tonsillar cancer is 89%, 55%, 49%, and 30% for T1 through T4 lesions respectively.

Base of tongue tumors are usually quite a challenge for the head and neck cancer practitioner. These tumors remain asymptomatic for a long time, usually present in advanced stages, have regional lymph node involvement (>60%), and have a tendency to metastasize to both sides of the neck (20%) (Fig. 45.9). Most of these tumors require a multidisciplinary approach and treatment. In early tumors it might be possible to resect the tumor transorally combined with neck dissection. Nearly 50% of the tongue base can be removed with very good functional results. Resection can be done using

FIGURE 45.9 Right neck mass. Primary tumor was asymptomatic base of tongue cancer that was found during exam under anesthesia in an otherwise asymptomatic elderly woman.

surgical laser or a more conventional method. Very good survival (52% at 5 years) and excellent functional results (92% could tolerate a normal diet and 88% had understandable speech) can be expected using this method [171]. For larger tumors, resection often involves other approaches such as transhyoid, lateral pharyngotomy or mandibular swing. The need for postoperative radiation depends on characteristics of the tumor, margins, and degree of involvement of lymph nodes. In general 5-year disease specific survival for tongue base tumors using surgery is reported as 65% [169]. This is quite comparable to primary radiotherapy [172].

Due to significant morbidity of surgery in most tumors, primary radiotherapy has become the method of choice in most cases. A combination of external beam radiation and brachytherapy has been an effective treatment both in maintaining function and offering comparable survival to other methods [173]. In general, more advanced tumors are treated with radiation to primary sites, neck nodes including retropharyngeal nodes, and in case of positive nodes, planned neck dissection after radiotherapy. Adding chemotherapy to radiation has shown an added benefit in local control and survival. The most effective method consists of concurrent chemotherapy and the most effective agents are platinum based chemotherapeutics [3, 174]. Primary surgical therapy is not used as often nowadays to treat advanced tumors. Treatment usually requires mandibulotomy to gain access and may involve total glossectomy, supraglottic, or even total laryngectomy and the need for free flap tissue transfer. Neck dissection is performed at the time of resection almost routinely. A significant number of patients will require adjuvant radiation to cervical lymph node beds. As it is apparent from the extent of surgery, functional consequences are quite devastating and patients will have significant difficulty in speech and swallowing. It has to be noted also that primary radiation and chemotherapy is not without complication and a number of patients will be afflicted with xerostomia, loss of taste, temporary and permanent dysphagia, pharyngeal or esophageal stenosis, osteoradionecrosis, and radiation induced malignancies. These issues show clearly the burden of this disease and its treatments on patients and the practitioners. The most recent data shows disease specific survival of 65%, 54%, 44%, and 30% for stages I–IV respectively [175].

Management of Mandible

Management of the mandible is necessary in a few scenarios. The mandible can be directly involved with the tumor, or it may limit the access to the tumor. Because of these issues, a comprehensive and careful pretreatment evaluation of the mandible is necessary in all oral cavity and oropharynx tumors. Careful physical exam remains one of the best

FIGURE 45.10 Various types of marginal mandibulectomies: vertical, horizontal, and oblique cuts (Reprinted with permission from Shaha AR (1992) Marginal mandibulectomy for carcinoma of the floor of the mouth. *J Surg Oncol* 49:116–119).

methods for assessment of mandibular involvement [176]. A Panorex view of the mandible, although not accurate in determining the extent of disease, is still helpful in delineating the extent of resection and surgical planning. In recent years tremendous improvements in CT and MRI imaging techniques have been made. There is still controversy as to which modality is the best. In general, CT is quite specific, but might miss subtle invasions (false negative). MRI on the other hand, is very sensitive, but will overstate mandibular invasion. One strategy is to obtain the MRI first and if there is no evidence of invasion, the practitioner can be reassured the possibility is quite low. If there is still doubt, it might be necessary to proceed with CT scanning. On the other hand, most surgeons will obtain the CT as first modality because of its easy interpretation, great bone details, and lower cost. This is an ongoing debate and cases should be decided on their own specific characteristics [177]. The CT interpretation for the mandible may be difficult due to artifacts from dental fillings. Dentascan is another great technique for mandible evaluation. PET/CT in recent years has been commonly utilized. Its role in finding mandibular invasion has not yet been well determined. SPECT imaging is used in some centers, mostly in Europe as an accurate modality to find mandibular invasion [178]. This modality is not being commonly used in the US.

The mode of tumor spread to the mandible has been studied extensively and our understanding of this process has evolved through the years. It was first believed that tumors spread to cervical lymph nodes through the lymphatic channels that perforate the periosteum and bony structure of mandible. Nowadays we know that tumors invade the mandible directly. There are two patterns, erosive and infiltrative. The infiltrative pattern happens in more advanced cases and has a much worse prognosis. Tumors travel in the mucosa and submucosa until they reach the periosteum. In dentate patients tumor cells migrate through dental sockets into the mandible. In edentulous patients tumors enter the mandible by moving to the occlusal surface first and then through the dental pits [179].

There is always debate regarding the extent of mandibulectomy. Traditionally, most bony invasions were treated by segmental mandibulectomy. Many studies have shown that as long as negative margins are acquired, marginal mandibulectomy is as effective as segmental mandibulectomy [179–182]. Marginal mandibulectomy can be achieved via a horizontal, vertical, or oblique cut (Fig. 45.10). The oblique cut has a few advantages. Retention of a strong mandible remnant and better tumor clearance are among those. The defect can usually be closed by advancement of adjacent mucosa or split thickness skin graft if necessary. Very small defects can be left open to heal by secondary intention or use of Alloderm and larger defects might need a free tissue transfer flap for optimal functional results.

If obtaining negative margins necessitates segmental mandibulectomy, the defect is routinely filled with bone containing a free tissue transfer. The most commonly used donor sites are the fibula, iliac crest, and scapula. These microvascular flaps tolerate radiotherapy quite well and cosmetic and functional results are quite good [183]. There is also possibility of dental implants after completion of therapy. Fibula free flap is the most commonly used technique and osseointegration works very well with the fibula. Many studies have shown similar success rate for free tissue transfer in elderly population. Most important risk factors are medical comorbidities and ASA class of patient [184, 185].

When there is a need to perform mandibulotomy to gain access to tumors of the oral cavity or oropharynx, the preferred sites are midline or paramedian. Lateral mandibulotomy is not recommended since it cuts the mandibular nerve and artery. A paramedian site is better than midline since the inferior alveolar nerve and artery can be preserved, genial muscles can be spared, the osteotomy site can be placed in the natural space between canine and incisor teeth and avoid dental extraction, the osteotomy site is outside the radiation field and finally the segments can be fixed adequately with plates or wires. After the osteotomy is done, a mandibular swing is performed and the mucosa of the floor of the mouth

is incised along the medial aspect of the mandible toward the tumor. This approach gives good exposure to parapharyngeal tumors including the deep lobe of the parotid. The cosmetic and functional results are quite good in experienced hands [186]. Segmental mandibulectomy is not recommended solely to gain access.

Osteoradionecrosis is one of the devastating complications of radiotherapy. Treatment is usually difficult, lengthy, and less than satisfactory. Prophylactic measures such as careful dental evaluation and extraction of unhealthy teeth before treatment, fluoride treatment, and regular follow-up during radiotherapy are quite important. Sometimes it is difficult to distinguish between recurrent tumor and osteoradionecrosis. More recently, PET scanning is used as a helpful modality to distinguish between these two [187]. Early limited osteoradionecrosis may respond to debridement, long term antibiotics, extensive oral irrigation, and hyperbaric oxygen. For more extensive cases, surgical excision and immediate reconstruction with free tissue transfer might be the only option [188].

Hypopharynx

Tumors arising from the hypopharynx are rare. The most common subsite is the pyriform sinus followed by the posterior pharyngeal wall and post-cricoid region. These tumors can remain asymptomatic for extended periods of time and the majority are diagnosed in advanced stages. Almost two-thirds of patients already have cervical lymph node involvement at diagnosis. It is also not uncommon for these tumors to metastasize bilaterally, since the hypopharynx has a rich lymphatic plexus. Because of these characteristics, most of these patients will require multimodality treatments. If surgery is used as primary treatment, depending on the extent of disease, there are several options. For early stage, small tumors (T1 and T2), partial pharyngectomy with either primary closure or myocutaneous flap or free flap is possible. Based on size and location of the lesion it might become necessary to perform partial laryngopharyngectomy or supraccricoid hemilaryngectomy. For larger lesions, total laryngopharyngectomy is used. If the tumor has spread to the cervical esophagus, total laryngopharyngoesophagectomy is performed. Reconstruction of such defects is achieved by free jejunal flap in laryngopharyngectomy and gastric pull-up and pharyngogastrostomy in laryngopharyngoesophagectomy cases. In all surgical methods, neck dissection is performed from level II to IV. Many patients will still require adjuvant radiotherapy, which will improve locoregional control and survival. Because of obvious morbidity of surgical treatments, it is quite common to treat these tumors primarily by radiotherapy or chemoradiotherapy. The results of these approaches are not as good as radiotherapy for laryngeal cancers [189, 190]. Surgery with postoperative radiation offers

similar locoregional control and survival rates to definitive chemoradiation; however, the rate of larynx preservation is higher in the chemoradiation group. Unfortunately the retained organ is not always functional and a significant number of patients will suffer from dysphagia and laryngeal dysfunction [190]. The overall prognosis for hypopharyngeal tumors is quite poor. The 5-year survival for N0–N1 disease is around 28–57% and for N2–N3 disease is 0–20%. These numbers are similar between different treatment modalities. Hypopharynx cancers remain a challenging topic for head and neck cancer practitioners and these patients should be considered for clinical trials of new modalities if possible.

Larynx

Laryngeal cancers are divided into three groups. Most common are glottic (51%), followed by supraglottic (32%), and subglottic (2%). The remainder of cases are either overlapping the two regions of the larynx (4%), or arise from the epiglottis (1%), or laryngeal cartilage (1%) [191].

In recent years significant improvements and changes have occurred in the management of laryngeal cancers due to seminal studies and introduction of new surgical techniques. In general, laryngeal cancer is divided into early and advanced stage for management purposes. In early laryngeal cancer, the emphasis is on using one modality and preserving maximal function without jeopardizing the oncologic principles of treatment. In advanced cases, multimodality treatment is used and the patient is given the best chance of preserving function and long term survival by a combination of chemotherapy, radiation, and surgery.

Glottic cancer has the best chance of being detected early. Lesions in this region become symptomatic at an early stage (hoarseness). This feature, combined with the fact that vocal cords have sparse lymphatic plexus and lymph node spread is not common, gives this group the best prognosis. Surgery and radiation are equally effective in treating T1 and T2 glottic tumors. Surgical treatments include endoscopic CO₂ laser excision in small tumors, and partial laryngectomy or hemilaryngectomy in larger lesions. The voice quality and cure rates after these procedures are excellent. Using transoral excision the 5-year local control rate is in range of 83–93% for T1 lesions and 73–89% for T2 lesions. These favorable results translate into disease specific survival rates of 96–99% for T1 lesions and 83–97% for T2 lesions [192]. Voice quality is best with endoscopic laser excision. Definitive radiotherapy is equally effective in treating early glottic cancer. There is no need to radiate the lymphatic basins of the neck since the incidence of lymph node metastases is extremely low. The voice quality is better than partial laryngectomy procedures. The results are extremely good. Five-year

regional control is 85–94% for T1 and 68–80% for T2 lesions. Disease specific survival again is in the range of 93–98% for T1 lesions and 70–88% for T2 lesions. In cases of radiation failure, salvage surgery with either partial or total laryngectomy is successful 60–97% of the time [193, 194]. It is important to pay careful attention to anatomic details of the tumor before choosing one modality over another. The most suitable tumors are the ones in the middle third of the vocal cords. Hypomobility of cords, suspicion of deeper involvement, and involvement of the anterior commissure are considered adverse factors for primary radiation therapy. Some histologic types are also relatively resistant to radiation (verrucous, adenocarcinoma, and sarcoma) and therefore should be treated surgically.

Early supraglottic cancers on the other hand have an increased risk of lymphatic spread and cervical lymph nodes are routinely addressed at the time of treatment of the primary tumor. The tendency is to use one modality to treat both primary sites and lymphatic basins. Definitive radiotherapy can be used to treat early supraglottic cancer. Different series have reported excellent success rates of 80–100% in T1 lesions and 70–85% for T2 lesions [195, 196]. The best results are achieved in small superficial tumors. Primary surgical treatment is also quite effective in treating early supraglottic cancer. Transoral laser excision is used with excellent results (90–95% for T1 and 70–80% for T2 lesions) [197, 198]. Elderly patients tolerate this procedure quite well and the incidence of complications is not higher than general population [199]. This modality can be used in conjunction with neck dissection or postoperative adjuvant radiotherapy [200]. In one series, use of adjuvant radiotherapy in T2 lesions resulted in 97% control of the primary site [198]. Another mode of surgical treatment is open partial laryngectomy. This modality has been studied extensively and the results are consistently good [195]. In this procedure the entire supraglottic unit including the epiglottis and the aryepiglottic folds down to the false vocal cords with the overlying thyroid cartilage and the intervening preepiglottic space are removed. Similar to transoral excision, it is important to address lymphatics by bilateral neck dissection from levels II to IV. The quality of voice is quite good. Not all patients are good candidates for this procedure though, since there is a risk of postoperative aspiration and swallowing problems. Unfortunately incidence of aspiration is higher in older patients and this fact makes selection of suitable patients more complicated [201]. Early subglottic cancer is seen extremely rarely and there is not much evidence in outcomes of treatment.

Advanced laryngeal cancer is one of the areas of head and neck cancer that has undergone revolutionary changes in management. Traditionally, advanced tumors (T3 and T4) were treated by total laryngectomy and adjuvant radiation.

Tumors with evidence of cartilage involvement are not good candidates for definitive radiation therapy since the recurrence rate is quite high. In 1991, a study by the Department of Veterans Affairs compared induction chemotherapy with 5-fluorouracil and cisplatin, and radiation to surgery and adjuvant radiation in previously untreated stage III and IV laryngeal cancer [202]. In this study two-thirds of patients responded well to chemotherapy and larynx were preserved. Survival was similar to the laryngectomy and radiation group. Later on, another study showed that concurrent chemotherapy is better than induction chemotherapy in larynx preservation (88% vs. 75%) and locoregional control (78% vs. 61%); however, there was no difference in survival and concurrent chemotherapy had more toxicity [203]. On the basis of these studies, it is a common practice now to treat advanced laryngeal cancer with concurrent chemoradiation. A few notes of caution should be considered before adopting organ preservation protocols. These protocols are not as effective in treating T4 tumors. Toxicity is quite high and in most cases they offer only modest survival advantage (4–6% only in concurrent protocols) [3]. Concurrent chemotherapy is also not as effective in older patients [3]. Detecting recurrent tumors in cases of chemoradiotherapy can be difficult since there are radiation changes that can mimic recurrence. The most commonly used modality is PET scanning and the results are encouraging. The sensitivity of FDG-PET is 84–100% and specificity is 61–93% for detecting recurrent cancer [204]. Salvage total laryngectomy and adjuvant radiation is used to treat organ preservation failures. In general up to 40% of patients in organ preservation protocols eventually require salvage surgery. Surgery is technically more difficult and the rate of complications in this setting is quite high (30–60% for wound problems and pharyngocutaneous fistulas). The 5-year survival is usually around 35% after salvage surgery [205–208]. A pectoralis muscle flap may be used to buttress the suture line.

Recurrent and Metastatic Cancer

A significant number of patients with locally advanced head and neck cancer will develop locoregional or distant relapses (Fig. 45.11). This usually occurs in first 2 years after treatment. Salvage surgery is an option for those who have resectable locoregional disease [208]. Resection of a recurrent tumor should encompass the entire initial extent of the primary tumor rather than the localized recurrent nidus. Recurrent tumors in the skull base or the ones invading prevertebral fascia or adhere to vertebral bodies are usually considered non-resectable. Re-irradiation with or without chemotherapy has also been investigated [209] and has shown

FIGURE 45.11 Advanced recurrent metastatic cancer in the neck after primary treatment. Note extensive involvement of skin.

better results than observation after salvage surgery. By far the most common method of treatment is chemotherapy, however. The goal is to extend survival and provide symptom palliation. Many agents such as methotrexate, bleomycin, carboplatin, and fluorouracil have been used as single agents in recurrent and metastatic disease [210]. Most trials are small and gains are modest. Two drug combinations improve response rates, but there is no gain in survival [210]. Fluorouracil plus cisplatin is the most commonly used combination. Taxanes plus cisplatin also shows equal results in recurrent cases but not superior to fluorouracil plus cisplatin [211]. Currently there is no standard second-line regimen for recurrent head and neck cancer. Addition of cetuximab to cisplatin and fluorouracil has shown promise [212]. Cetuximab has been also effective in platinum resistant tumors [213]. Gefitinib (EGFR-tyrosinase inhibitor) has also been used in clinical trials, but did not show any survival benefit over intravenous methotrexate [214].

Salivary Gland Tumors

The salivary glands are divided into major and minor. Major glands are the parotid, submandibular, and sublingual. Minor salivary glands are distributed throughout the mucosa of the upper aerodigestive tract. The highest concentration is in the hard and soft palate [215]. The majority of parotid tumors are benign (75%), while almost half of other submandibular salivary gland tumors are malignant. In contrast, a majority of minor salivary gland tumors are malignant (80%) [215]. Salivary gland tumors are relatively rare and there is no specific consideration in management of elderly patients. The general principles of treatments are the same in this population.

Patients with malignant tumors or tumors of minor salivary gland tend to be slightly older than patients with benign tumors or those of parotid gland [216].

The parotid gland is the largest major salivary gland. It is also the most common site of salivary gland tumors (65% of all salivary gland tumors). The gland is between the dermis laterally and the masseter muscle and sternocleidomastoid muscle medially. The lateral parapharyngeal space is medial to the parotid gland. The facial nerve divides the gland into two artificial lobes. The bulk of the gland is superficial to the nerve and most tumors arise from this portion. Thorough knowledge of facial nerve anatomy and its course is crucial to successful parotid surgery. The facial nerve exits the skull through the stylomastoid foramen and passes lateral to the styloid process. The main trunk lies at the junction of three anatomic structures: the posterior belly of digastric muscle, the bony auditory canal, and the tip of mastoid process. The nerve then enters the parotid gland and divides into the upper zygomaticotemporal and lower cervicomandibular divisions. By the time the nerve exits the gland it has been divided into five branches: temporal, zygomaticorbital, buccal, mandibular, and cervical. Two branches are of critical functional importance – the orbital branch innervating the eyelid, and the mandibular branch innervating the lip. Injury to these two branches causes considerable cosmetic and functional disability. The parotid duct (Stensen) exits the gland anteriorly over the masseter muscle and then pierces the buccinator muscle to enter the oral cavity opposite the second maxillary molar on the buccal mucosa.

The submandibular gland is the second largest major salivary gland. It lies in the submandibular triangle on the hyoglossus muscle. Each gland is divided into two lobes by the posterior edge of the mylohyoid muscle. Wharton's duct runs from the deeper portion of the gland anteriorly under the mylohyoid muscle and drains into the floor of the mouth just lateral to the frenulum of the tongue. Three nerves are in proximity to the submandibular glands: lingual, hypoglossal, and ramus mandibularis. It is important to pay close attention to function of these nerves in the management of submandibular tumors.

Sublingual glands are the smallest of the three. They are located under the mucosa of the floor of the mouth above the mylohyoid muscle. The borders are the mandible laterally, the genioglossus medially, and the submandibular gland posteriorly. There are many minor sublingual ducts that open into the oral cavity (ducts of Rivinus). Some of these ducts join each other to form the major ducts of Bartholin. The ducts of Bartholin join the submandibular duct. The lingual nerve comes down laterally to the anterior end of the sublingual gland and runs along its inferior border. It then runs parallel to the submandibular duct until ascending into the tongue.

Diagnostic Work-up

A physical examination can give valuable information on most major salivary gland tumors, especially in the parotid. A hard fixed mass in the parotid gland is always suspicious for malignancy. Paresis or paralysis of the facial nerve is almost always an indicator of malignancy since benign processes do not easily cause paralysis even when they become quite large.

The most commonly used imaging modalities are CT scan and MRI. CT scan is available and quicker to perform. It is better in delineating bone destruction and invasion. MRI in general is superior to CT. It provides better anatomical detail and superior soft tissue differentiation. MRI is particularly helpful in deep lobe parotid tumors, minor salivary gland tumors, and vascular and neurogenic tumors [217]. PET scanning is usually not used in initial evaluation of salivary gland tumors.

FNA of salivary gland tumors can be quite helpful. Overall sensitivity of FNA ranges from 85 to 99% and the overall specificity is from 96 to 100% [46, 218–220]. FNA is more accurate for benign lesions than malignant ones. It is also very good in distinguishing between salivary and non salivary processes (lymphoma). Occasionally, a benign lesion such as mixed tumor can be interpreted as adenoid cystic carcinoma. Usefulness of FNA is highly dependent on the experience of cytopathologist. In general, FNA is a simple, easy to perform technique that can provide valuable information to better manage the lesion. FNA results can change the management of major salivary gland tumors in almost 35% of cases [221].

Staging of major salivary gland tumors is described in Tables 45.6, 45.7, 45.9, and 45.10. Minor salivary gland tumors are staged similar to squamous cell carcinomas.

Benign Tumors

Most benign tumors occur in the parotid gland. The most common are mixed tumor followed by Whartin's tumors. Oncocytoma, benign lymphoepithelial, and myoepithelial lesions are rarely seen. Almost 80% of parotid tumors are benign mixed tumors. These are called mixed since they show morphologic diversity with epithelial and connective tissue components such as myxoid, chondroid, and fibroid. They grow slowly in general, but occasionally rapid growth is observed in some patients with longstanding tumors. This might be due to development of carcinoma in a benign mixed tumor (carcinoma ex-pleomorphic adenoma). This situation can occur in 1–7% of cases [222]. The majority of these tumors are located in the superficial lobe of the parotid gland. They can also occur in minor salivary glands of the palate and

upper lip. Many other sites have also been reported as origins of mixed tumors (buccal mucosa, base of tongue, parapharyngeal space, and nasal cavity). Pleomorphic adenoma is also the most common benign tumor of the lacrimal gland.

The most appropriate treatment is superficial parotidectomy with preservation of the facial nerve. In cases of deep lobe tumors, facial nerve function can be preserved and surgery usually involves enucleation of the tumor. On occasion, a very large deep lobe tumor might require a lower lip split incision and mandibulotomy for access. The principle is to remove the tumor with negative margins to avoid recurrence. Tumors that are enucleated or incompletely removed are at risk for recurrence. Any mass in the parotid area should be considered a parotid tumor and adequate treatment consisting of superficial parotidectomy and facial nerve identification and preservation should be performed.

Papillary cystadenoma lymphomatosum or Whartin's tumor is the second most common benign salivary gland tumor and consists of 10–15% of parotid tumors. These tumors are found exclusively in the parotid gland and are believed to originate from periparotid or intra parotid lymph nodes. Whartin's tumors are more common in men and are associated with cigarette smoking. Bilateral tumors can occur in 10% of cases. The risk of malignant transformation is extremely low. FNA is quite accurate in diagnosing Whartin's tumors. Treatment is superficial parotidectomy with facial nerve preservation.

Oncocytomas are rare tumors of the parotid gland (1%). They are fleshy, slow growing tumors. In the parotid they are usually well circumscribed and encapsulated but not in minor salivary glands. These tumors can show high uptake of technetium-99m and will be enhanced in radionuclide scans. Surgical excision with negative margins is the treatment of choice. Oncocytomas are resistant to radiation.

Myoepitheliomas are quite rare (less than 1%). They can occur in major and minor salivary glands. The tumor consists of myoepithelial cells exclusively. Sometimes it is difficult to distinguish myoepitheliomas from mixed tumors clinically since they present a slow growing painless mass. They should be differentiated from plasmacytomas and other tumors with spindle cells (neurilemoma, fibroma, meningioma, and leiomyoma). They usually occur in the third to sixth decade of life and there is no gender predilection. Treatment is surgical excision.

Malignant Salivary Tumors

Malignant salivary tumors are rare. They consist of 6% of head and neck cancers and 13% of salivary gland tumors. The most common type is mucoepidermoid carcinoma followed by adenoid cystic carcinoma and adenocarcinoma.

FIGURE 45.12 Hematoxylin-Eosin staining of adenoid cystic carcinoma. This slide shows cribriform pattern of tumor that is associated with lower grade and better prognosis.

Mucoepidermoid carcinomas originate in the salivary duct epithelium and comprise 44% of parotid malignancies. They are classified as low, intermediate, and high grade histologically. Low grade tumors act more like benign mixed tumors with slow growth, low recurrence rates, and rare distant metastases. Superficial parotidectomy with preservation of the facial nerve is the adequate treatment and 5-year survival is as good as 95% [223]. High grade tumors on the other hand show local invasion, facial nerve involvement, and lymph node metastases as high as 50% at presentation. The prognosis for this group is dismal [223].

Adenoid cystic carcinoma constitutes the most common malignancy of the minor salivary gland and submandibular gland and 10–15% of malignant parotid tumors. They show three distinct histologic patterns: cribriform, tubular, and solid. Cribriform pattern has the best prognosis and solid, the worst (Fig. 45.12). Adenoid cystic carcinoma can show unpredictable behavior. It is usually characterized by slow growth, neurotropism, local recurrence, and distant metastases. Cervical metastases are infrequent, but late distant metastases are common [216]. Treatment is surgical excision and postoperative radiation. Cervical lymph node dissection is usually not performed.

The malignant mixed tumor is a category consisting of carcinoma ex-pleomorphic adenoma, carcinosarcoma, and metastasizing mixed tumor. These are similar but distinct malignancies. The malignant mixed tumor category accounts for 5–12% of salivary gland malignancies. Carcinoma ex-pleomorphic adenoma is a carcinoma arising from a longstanding benign mixed tumor. True malignant mixed tumors show elements of carcinoma and sarcoma simultaneously. They are usually grouped with carcinoma ex-pleomorphic adenomas. Metastasizing mixed tumors are characterized by primary tumor and metastases that appear completely benign under the microscope. Cervical metastases are present in 15% of this category at presentation. Treatment is surgical excision including cervical lymphadenectomy and postoperative radiation.

FIGURE 45.13 Large left parotid tumor. The marking shows the incision for standard superficial parotidectomy (modified Blair's incision).

Treatment of Salivary Tumors

Surgery

Surgical excision is the mainstay of treatment for malignant and benign salivary tumors. The minimal operation for parotid lesions is superficial parotidectomy with identification and preservation of the facial nerve (Fig. 45.13). Enucleation is not recommended uniformly. Most tumors of the superficial parotid can be addressed with this modality. Deep lobe tumors are more challenging. Total parotidectomy might be necessary to remove the tumor in its entirety. Every effort should be made to preserve a functioning facial nerve. Most of the time with careful dissection, a deep lobe parotid tumor can be removed without injury to the facial nerve branches. If the bulk of the tumor is in the parapharyngeal space and adjacent to the pharyngeal wall, a mandibulotomy approach might be a more suitable choice for exposure and excision of the mass. If the nerve is adherent to the tumor but functional, it can be peeled off carefully. In these cases, postoperative radiotherapy is indicated. If the nerve has already been invaded or paralyzed, or in rare cases a functioning nerve has to be sacrificed, immediate nerve grafting using cable interposition grafts from the greater auricular nerve, or cervical plexus, or sural nerve should be attempted. In order to protect eye function and closure, a gold weight can be implanted in cases of nerve sacrifice or paralysis due to tumor invasion.

Excision of submandibular gland tumors requires removal of the entire contents of the submandibular triangle. This becomes complicated due to the presence of three important nerves in this area, the ramus mandibularis, hypoglossal, and lingual nerves. If the tumor is close or attached to mandible, removal of the periosteum or even a segment of mandible is necessary. As part of the procedure, supraomohyoid neck dissection might be performed.

Minor salivary gland tumors are treated by wide local excision. This might require full thickness excision or infrastructure partial maxillectomy in hard palate tumors. The resultant defect should be covered with a dental obturator.

Palpable nodes at presentation should be addressed with modified or radical neck dissection. Elective neck dissection from level I to III is recommended for tumors >4 cm, high grade mucoepidermoid carcinoma, squamous cell carcinoma, adenocarcinoma, and undifferentiated carcinoma. For other patients if a transcervical approach is used, elective neck dissection should be included. If suspicious lymph nodes are encountered at the time of surgery, it is recommended that a comprehensive neck dissection be performed.

Radiation

Radiation is being used frequently nowadays in treatment of salivary gland tumors. It improves locoregional control and overall survival [224]. Indications for postoperative radiotherapy include advanced inoperable cancer, high-grade, high-stage primary tumor, positive margins, deep lobe malignant tumors, lymph node metastases, and tumor spillage at the time of surgery. Also in high-stage adenoid cystic carcinomas, due to the high recurrence rate, postoperative radiotherapy is recommended. Neutron therapy has shown improved locoregional control in adenoid cystic carcinoma in comparison to traditional photon irradiation (56% vs. 17%). It also improved 5-year survival for patients with adenoid cystic carcinoma and acinic cell carcinoma. However, 5% of patients experienced severe toxicity [225]. Neutron therapy is available only in a few centers in the US and is generally used for inoperable salivary tumors.

Chemotherapy

There is scant experience with chemotherapy in the treatment of salivary gland tumors. Fluorouracil, cisplatin, doxorubicin, and cyclophosphamide have been used in few patients [226]. The initial response is usually around 50%, but only lasts for 7–10 months [227]. In patients with complete response, survival was >19 months [228]. Overall success of chemotherapy has been disappointing. Concomitant use of radiation and chemotherapy might show some improvement in survival over radiation alone [229]. Immunotherapy with EGFR blockers might also become an option for treating salivary gland tumors [230].

Prognosis

Tumor stage is the most important prognostic factor [216, 231]. The overall 10-year survival rates for stages I–III are approximately 90%, 65%, and 22%. Grade is also important. Low grade tumors have 10 year survival as high as 90%, while high grade tumors survival rates are only around 25%. Adenocarcinoma, malignant mixed tumor, adenoid cystic, and squamous cell carcinomas have worse prognosis than acinic or low grade mucoepidermoid tumors. Submandibular and minor salivary gland tumors are more aggressive than parotid tumors in general. Gross nerve involvement, and bone and skin invasion have also been implicated as adverse prognostic factors [231, 232].

Follow-up of Head and Neck Cancer Patients

Patients treated for head and neck cancer need close and regular follow-up. The standard regimen consists of visits every 6–8 weeks in the first year followed by 2–3 month visits in the second year, 3–4 month visits in the third year, and biannual or annual visits thereafter for life. The extent of investigation in each visit is a matter of debate. Each patient should be evaluated individually with a program tailored to his or her particular needs. Some patients with deep tumors might require CT scanning while others will be adequately followed by physical exam. Chest radiographs are usually adequate to monitor for pulmonary metastases. The radiographs should be interpreted carefully and compared to previous studies. Routine endoscopy of the aerodigestive tract is not of proven value and should be performed in select cases or when symptoms suggesting problems in the lungs or esophagus arise. Patients treated with an organ preservation approach by chemoradiotherapy are best followed with careful physical examination along with PET scan. PET scan and specially PET CT is being used more often as a sensitive tool for follow up of patients [204]. Negative results are usually quite reassuring; however, positive changes have to be interpreted carefully to rule out other causes such as inflammation or infection.

Section VI

Respiratory System

Chapter 46 Invited Commentary

Earle W. Wilkins Jr.

A life span of 90 years provides an opportunity to look at the past, to compare surgery of the chest today and what it was like 25 or more years ago. Such a review should tell us what we have learned and what we do need to learn yet.

Early History

Certain mileposts stand out. The principles of one-stage lobectomy with individual ligature technique were formulated by Harold Brunn of San Francisco in 1929 [1]. Evarts Graham of St. Louis performed the first successful pneumonectomy for bronchogenic carcinoma in 1933 [2]. Edward Churchill of Boston, in collaboration with his fellow Ronald Belsey, defined the technique of segmental lobectomy in 1938 [3]. In the related field of esophageal surgery, William Adams and Dallas Phemister of Chicago had successfully carried out a resection of a carcinoma of the distal esophagus with intrathoracic esophagogastric anastomosis, also in 1938 [4]. Further historical details in the evolving story of surgery of the respiratory tract are provided in “General Thoracic Surgery: History and Development,” Chap. 1 in Pearson’s *Thoracic Surgery*, 2nd ed. (2002).

The Past: 1944–1985

By the beginning of my days in surgery, pulmonary resection had become an established and safe technical procedure. These decades saw improvements in the fields of diagnosis, technical details of surgery including instrumentation, advances in anesthesiology, the introduction of antibiotics, and particularly in the postoperative care of the patient.

1. *Extent of surgical resection:* Until 1950, Graham’s pneumonectomy was the standard operation for lung cancer. A somewhat revolutionary and initially disputed report from Churchill and Richard Sweet (1950) [5] demonstrated that lobectomy, when technically possible, was an adequate and potentially curative procedure. Both of these men, my mentors, were true pioneers in the field of thoracic surgery; both became president of the American Association for Thoracic Surgery. A later president, Leo Eloesser, commented “the attempt to eradicate cancer by progressively increasing the anatomic limits of operation is not the right road to follow.” Thus, lobectomy became the operation of choice.
2. *Staging:* As it became clear that invasion of lymphatics and lymph node metastases were determinants in the possibility of cure for bronchogenic carcinoma, the concept of preoperative staging was developed. An early technique, popularized by Griffith Pearson of Toronto, was mediastinoscopy [6]. This permitted direct visualization and biopsy of mediastinal and bronchial lymph nodes. Computed tomographic (CT) scanning provided a noninvasive method of assessing the mediastinum for the presence of enlarged nodes, but without pathologic tissue diagnosis. A more recent scanning technique, positron emission tomography (PET) is particularly helpful in assessing mediastinal node involvement. Precise information provided by these studies guided the decision of surgery vs. radiation or other nonoperative therapy.
3. *Postoperative care:* The era saw an evolution of postoperative care from the early recovery room to the intensive care unit (ICU). The original ICU established in 1958 at the Massachusetts General Hospital was planned for the care of postthymectomy patients with myasthenia gravis. It proved invaluable in the care of patients with pulmonary resections, especially those undergoing pneumonectomy. Respiratory physical therapy for the pulmonary patient, both pre- and postoperatively, became an integral component of care. A whole spectrum of new antibiotics became available for prophylactic use.
4. *Anesthesia:* Not to be forgotten in the progress of managing surgery for the respiratory patient was the role of the

anesthesiologist. Measurement of arterial blood gases became routine. The use of pulse oximetry and continuous observation of arterial blood pressure and electrocardiographic tracing became regular monitoring techniques. The depth of necessary analgesia could be managed by a host of newer pharmacologic agents. The employment of the double-lumen endotracheal tube allowed the thoracic surgeon better technical access to mediastinal structures in his intraoperative dissections.

5. *The endotracheal tube* underwent a major modification. An unfortunate increase in the incidence of postintubation tracheal strictures proved to be the result of pressure ischemia of the tracheal wall resulting from tubes with the noncompliant inflatable cuff. Grillo and Cooper developed the large volume, low-pressure cuff, the so-called “floppy” cuff, which not only avoided the early postintubation stricture but also permitted longer term ventilatory mechanical assistance without serious damage to the trachea [7].
6. The *key* for developments in this period is encompassed in the word *Safety*: a safe conduct of the operated patient via safer selection, safer extent of operation, safe anesthesia, and safe postoperative care.

The Present Day: 1986 Onward

This is a term used since my departure from the chest operating scene. Happily, surgical care of the respiratory patient marches steadily forward. This includes in particular the geriatric patient.

1. *Video-assisted thoracoscopic surgery (VATS)*. This technique is certainly the striking advance in the field of general thoracic surgery in recent decades. It makes possible an entirely different access to surgery within the thoracic cavities, perhaps as big a change as in all the preceding half century. The utilization of multiple mini-incisions, remarkable magnifying fiber-optic visualization, and an impressive array of specially devised instrumentation make for a more comfortable postoperative patient and a shorter stay in the hospital. It is a strangely new technique for the older surgeon, requiring looking horizontally at a monitoring screen rather than downward at the patient’s chest.

In general, VATS resections may be preferred for lobectomies, segmental, and other nonanatomic excisions, and for an excellent approach to thymectomy for myasthenia and for most thymic tumors. It is not a technique for large pulmonary tumors, for sleeve or other extended resections, such as the approach and access to superior sulcus tumors. Many skilled VATS surgeons object to pneumonectomy through this approach. The surgeon must

always be prepared to convert to open thoracotomy for cases with difficult anatomy, extent of tumor, or unexpected event such as major hemorrhage.

2. *Induction chemotherapy*: It has long been a policy to irradiate the mediastinum of patients in whom positive lymph nodes were found at time of resection (stage III). Although this adjuvant (postoperative) therapy has enhanced local control, it has not resulted in improved long-term survival. Similarly, adjuvant chemotherapy alone has not proved beneficial in stage III patients. The result has been a shift to the use of induction (preoperative) chemotherapy in an effort to improve length of survival. Chemotherapy, either adjuvant or induction, with or without irradiation, has not proved curative in the absence of resection.

An encouraging development has been the increasing role of the surgeon in the study and analysis of results in the use of induction chemotherapy. He has become his own oncologist. Numerous current randomized trials with varying drug combinations, with and without irradiation, remain in the evaluation phase of study. The General Thoracic Surgical Club has taken on such evaluating reviews at its annual meetings. It is difficult for this “non-combatant” to comprehend clearly the results thus far. There is an apparent survival benefit in the use of adjuvant chemotherapy in resected patients with N1–N2 disease, and it is reasonably clear that patients resected for stage IIA disease derive survival benefit from induction chemotherapy or chemoradiation.

Again, thus far, it is difficult to anticipate cures. Its role in elderly patients is certainly far from clear. One must balance the often distressing side effects with survival time gained.

3. *Advances in surgical techniques*: By 1986, most surgical techniques dealing with lung cancer had become standard. Yet, there has been refinement in techniques in the recent era. The surgical management of superior sulcus tumors is one example. Operability, the likelihood of en bloc total removal of the tumor, improved with the use of induction chemoradiation and with the ease of resection facilitated by choosing the incisional approach. Depending upon the location of the primary tumor, the two commonly used approaches are the anterior cervicothoracic and the posterior.

Familiarity with the technique of sleeve bronchial resections has led to greater use of these parenchyma sparing procedures. They constitute another advance in the goal of avoiding pneumonectomy. This is especially desirable in the elderly patient avoiding higher rates of complications and limitations in life style. Bronchoplasty has become a standard procedure for the accomplished thoracic surgeon. The potential addition of carinal resection for so-called T4 tumors has been added to the surgeon’s skills. It usually is accomplished with a right

pneumonectomy and anastomosis of the distal trachea to the left main stem bronchus. It is a procedure used only when every other patient factor is favorable and only by the most skilled operator and anesthesiologist. It has limited use in the geriatric patient. The *key* summary for this era is a combination of improved patient comfort and ongoing efforts with combination therapies to increase lengths of survival. The question remains: what is the role for and the details of chemotherapy?

Personal Commentary

1. The *geriatric patient*, already self-selected by virtue of mere survival, is a reasonable candidate for lobectomy for cancer of the lung. This is especially true with the VATS technique. Pneumonectomy should be undertaken with urgent caution. Left pneumonectomy is certainly better tolerated than the right.
2. Preoperative staging, by scanning techniques and/or mediastinoscopy, is essential. The finding of N2 disease should raise an alert as to whether surgical resection is indicated in the elderly patient.
3. Preservation of as much lung parenchyma as possible is the *sine qua non* in resections in the geriatric patient. Where possible, segmental resection or nonanatomic wedge resection is acceptable.
4. The use of inductive or adjuvant therapy with resections of the lung is a debatable consideration in the elderly. It should be an individual, not a routine, decision based on physiologic and life-style considerations.
5. Contraindications to pulmonary resections arise from physiologic, not chronologic, age. Particular attention in evaluation of candidacy for operation must be directed to cardiovascular status, pulmonary function, and the presence of metabolic or other malignant disease.
6. Personal experience: In a review of 426 pulmonary resections (unpublished data), there were *four* hospital deaths in 81 pneumonectomies (4.9%), while in lobectomies, the mortality was 1.6%. Once again, where technically possible, lobectomy is the preferred operation. Special attention must be paid to the right pneumonectomy patient, whether geriatric or younger. Two of the mentioned mortalities resulted from bronchial stump leakage. Closure had been accomplished by the interrupted suture technique in patients who had accompanying mediastinal node dissections. Interruption of the arterial blood supply to the stump, related to the thorough mediastinal lymph node dissection, may have been a contributing factor in nonhealing.
7. Carcinoma of the lung remains the greatest cause of cancer deaths in patients of both genders. With maximal surgical therapy, no more than 20% of all such patients are being cured. The establishment of the optimum inductive or adjuvant therapy, chemotherapy and/or radiation remains a difficult goal. Promising new approaches are on the horizon. At the Massachusetts General Hospital, biopsies of lung cancers are being scanned for genetic mutations (*tumor genotyping*), information from which may guide the oncologist in selecting specific chemotherapeutic drugs (*targeted therapy*) for specific tumors.
8. The surgeon remains a key, perhaps *the* key figure in the curative management of lung cancer. He should not forget the words of Emily Dickinson:

*Surgeons must be very careful
When they take the knife,
Underneath their fine incisions
Lies the culprit – Life!*

Chapter 47

Physiologic Changes in Respiratory Function

Edward J. Campbell

Physiologic changes with age: pulmonary

Parameter	Change with age	Functional impact of change
Chest shape	↑ AP diameter Mild-mod kyphosis	No significant impact
Conducting airways	Calcification Mild ↑ size Mucus gland hypertrophy	Insignificant ↑ deadspace Minimal significance
Lung parenchyma	Enlarged alveolar ducts V/Q mismatch ↓ Elastic recoil	Similar to mild emphysema Decreased reserve
Bellows apparatus	↑ Chest wall rigidity ↓ Respiratory muscle strength	Increased work of breathing Highly individual
Ventilatory control	↓↓ Response to hypercapnia and hypoxemia	Impaired homeostasis under stress Signs of distress subtle

Most important messages in bold

AP anteroposterior; V/Q: ventilation/perfusion

A substantial proportion of the excess operative risk among elderly patients is attributable to respiratory complications. The excess risk is explained in part by structural and functional changes in the respiratory system associated with aging. These changes are progressive even in individuals who enjoy apparently good health and are most marked beyond 60 years of age.

In youth, healthy individuals have a physiologic reserve (a marked excess of functional capacity over the amount needed to meet metabolic needs at rest or with stress). The respiratory system draws on this reserve as its function declines with age. Aged individuals thus become vulnerable to the stress, disease, and injuries that are weathered much more easily by the young.

The routine activities of healthy elderly persons are not limited by this decreasing respiratory system function. Thus, the effects of age may not be apparent until they need to draw on their physiologic reserves during stress, such as postoperative recovery or complications. An awareness of the inevitable,

but possibly hidden, age-related changes in the respiratory system helps the surgeon anticipate and treat respiratory complications in elderly patients.

The purely age-related changes in the respiratory system are complicated by other accompaniments of aging. The lungs are exposed to a lifetime of environmental stresses, including tobacco smoke, respiratory infections, air pollutants, and occupational exposures to dusts and fumes. Elderly individuals also often have increasingly sedentary lifestyles and decreasing fitness.

As an introduction to the topics to be reviewed in this chapter, the various components of the respiratory system are shown in Table 47.1. Table 47.1 also contains introductory comments about structural and functional changes with age.

Airways and Lung Parenchyma Lung Shape

The lungs are closely applied to the chest wall, and their overall shape is determined by the chest wall shape. The increases in anteroposterior diameter of the lungs with age and the more rounded shape that results are presumably due to

TABLE 47.1 Respiratory system and changes with aging

Functional division	Components	Function	Change(s) with aging
Conducting airways	Airways not involved in gas exchange	Transport gas to and from lung parenchyma	Calcification and other minor changes
Lung parenchyma	Respiratory bronchioles through alveoli and supporting structures	Exchanges gas between alveoli and pulmonary capillaries	Enlarged alveolar ducts; ventilation–perfusion mismatching
Bellows apparatus	Chest wall and respiratory muscles	Provides support for lung structure and applies force to lung	Increased rigidity of chest wall, some decrease in respiratory muscle strength
Ventilatory control	Respiratory control center; carotid and aortic bodies	Alters ventilation to match metabolic needs	Markedly decreased responses to hypoxemia and hypercapnia

changes in the shape of the surrounding thoracic cage. These changes are not thought to have functional consequences.

Conducting Airways

The conducting airways consist of the air passages from the mouth to the level of the respiratory bronchioles. The volume of the conducting airways determines the anatomic dead space. Their size, shape, and branching pattern are the major determinants of airway resistance. The large cartilaginous airways show a modest increase in size with age, resulting in slight but probably functionally insignificant increases in anatomic dead space [1]. Calcification of cartilage in the walls of the central airways and hypertrophy of bronchial mucous glands are seen during advanced age, but these and other changes in the extraparenchymal conducting airways appear to have little or no physiologic significance.

Lung Parenchyma

The respiratory bronchioles and alveolar ducts undergo progressive enlargement with age, beginning as early as age 30 or 40 but observable most prominently after the age of 60 (Fig. 47.1). The proportion of the lung made up of alveolar ducts increases, and alveolar septa become shortened, leading to a flattened appearance of the alveoli. The proportion of alveolar air decreases as the volume of air in alveolar ducts increases [2]. The distance between alveolar walls (the mean linear intercept, or MLI) increases, whereas the surface/volume ratio of the lung decreases. As a result of these changes, the alveolar surface area decreases by approximately 15% by age 70.

Superficially, the morphologic changes in the lung with aging are similar to those observed with mild pulmonary emphysema. To be classified as emphysema, however, the anatomic changes must consist of airspace enlargement in

FIGURE 47.1 Histologic changes in the aging lung. Normal lung of a 36-year-old woman (*left*). Lung of a 93-year-old woman (*right*). Alveolar ducts are dilated, and shortening of interalveolar septa is observed (photomicrographs courtesy of Charles Kuhn III, MD, with permission of the Mayo Foundation).

the gas-exchanging zone of the lung (distal to the terminal bronchioles) and must show evidence that the airspace enlargement is due to alveolar wall destruction, with fusion of adjacent airspaces [3]. For a time, there was considerable debate as to the cause and classification of the airspace enlargement seen with advanced age. Debate centered on whether the airspace enlargement was a “senile” form of emphysema.

Pump [4] and several early authors thought they could identify “emphysematous” lesions in aged lungs. However, Pump studied only two lungs (from 78- to 80-year-old men), one of whom had been a heavy smoker. Ryan and colleagues resisted the term “emphysema” and called the age-related structural changes “ductectasia” because of the prominent finding of enlarged alveolar ducts [5]. Significant alveolar wall destruction as a cause of emphysema appears to be unlikely, as Thurlbeck and Angus have shown that the number of alveoli per unit area remains constant in mature lungs [2]. The latter authors considered the changes to be a “rearrangement of the geometry of the lung.” A National Heart, Lung, and Blood Institute Workshop on the definition

of emphysema weighed the available evidence and decided not to include age-related changes in the lung parenchyma under the definition of emphysema [3]. To avoid confusion and to simplify the nomenclature, they recommended use of the term “aging lung” to apply to the uniform airspace enlargement that develops with increasing age.

Mechanical Properties of the Lungs

The lungs exert an inward force in the intact thoracic cage. The retractile force of the lungs, or “elastic recoil,” can be measured during life by estimating the pleural pressure with an esophageal balloon. Measurements are taken at progressively decreasing lung volumes from total lung capacity (TLC) to functional residual capacity (FRC), when the airways are open and there is no airflow. The negative pleural pressure is generated by the lungs’ elastic recoil forces.

Figure 47.2 compares the elastic recoil pressures of a young man, a normal elderly adult, and a patient with emphysema. The normal elderly individual and the patient with

FIGURE 47.2 Static pressure–volume curves of the lungs illustrating elastic recoil forces and compliance. To generate these data, transpulmonary pressure (which reflects lung elastic recoil) is measured at various lung volumes with an esophageal balloon. At any lung volume, the recoil pressure is less in the aged than in the young individual. This results in a pressure–volume relation that is shifted upward and to the left. A curve for a patient with emphysema is shown for comparison. With emphysema, recoil pressures are much less than in normal elderly individuals, and lung compliance (the slope of the curve) is markedly abnormal (from Pride [6], with permission).

emphysema have a greater decrease in elastic recoil pressure than does a young person. This is reflected in the leftward shift of their pressure–volume curves [7, 8]. Emphysema produces a much greater loss of elastic recoil than is caused by aging alone.

There has been some disagreement as to whether aging changes lung compliance (the slope of the curve in Fig. 47.2) or, alternatively, is accompanied by a parallel leftward shift of the pressure–volume curve with aging (no change in compliance). There is general agreement if small changes in lung compliance do occur, they are not physiologically significant.

Changes in Lung Recoil Due to Surface Forces

The loss of surface area with age reduces the area of gas–liquid interface, resulting in a decrease in the surface tension forces. This ultimately causes a decrease in the lung elastic recoil. This change has important effects on lung function (especially on the function of small airways and expiratory flow).

Changes in Structural Macromolecules

Elastic fibers consist in large part of an extremely hydrophobic, highly cross-linked, and highly elastic macromolecule (elastin). They form a continuous skeleton that follows the airways and pulmonary vessels and extends to a fine meshwork in the alveolar septa [9]. These fibers are thought to contribute substantially to lung elasticity. The amount of elastin in the lungs has been studied in an attempt to determine the cause of decreasing lung elastic recoil with age. Analysis of whole lungs has revealed that the elastin content actually increases (rather than decreases) with age [10]. More recent evidence indicates that the increase in lung elastin with age is accounted for by an increase in pleural elastin; parenchymal elastin does not change [9].

Careful studies of the elastic fibers in the lung parenchyma by two independent methods have shown that they are remarkably stable following postnatal lung growth. Modeling of radiocarbon data [11] indicates that the “mean carbon residence time” in elastin is 74 years (Fig. 47.3). It is correct to consider that lung parenchymal elastin is stable over the human life span. These elastic fibers probably provide a metabolically inert scaffold for the structure of the lung. Thus, there are no age-related changes in lung elastin that provide an explanation for the decrease in elastic recoil forces observed in the elderly.

Although human studies have not been done, studies in rodents and birds suggest that lung collagen fibers, like elastic

FIGURE 47.3 Turnover of elastic fibers in human lung parenchyma. Radiocarbon (^{14}C) prevalence in lung elastin is shown on the ordinate, with zero being the level before atmospheric nuclear weapons testing began. Levels above zero reflect protein synthesis that has occurred since the 1960s (% Above Modern). The symbols are data from human tissues that exhibit rapid turnover, sampled during the years shown [11]. Each horizontal line represents an analysis of human lung parenchymal elastin from a single individual. The age at time of death is shown for each subject. The lengths and positioning of the solid portions of the lines correspond to timing and duration of fetal and postnatal lung growth, and the interrupted portions of the lines represent the remainder of the individuals' life spans. The vertical position of each line represents the ^{14}C prevalence measured in that sample. Note that the ^{14}C prevalence measured in the elastin samples reflects the ^{14}C prevalence in the biosphere during the period of lung growth. Individuals whose lungs had ceased growing before the nuclear weapons age had little nuclear weapons-related ^{14}C in their lung elastin, demonstrating that minimal lung elastin turnover occurred during adulthood (from Shapiro et al. [11], with permission).

fibers, are long-lived. Finally, although some qualitative changes in collagen during aging have been described (decreases in solubility and increases in intermolecular cross-links), they appear to have no relation to changes in lung elastic recoil.

Chest Wall

The chest wall becomes more rigid with advancing age [8, 12]. As can be seen in Fig. 47.4, the static pressure–volume curve of the chest wall is shifted to the right and is less steep (indicating decreased compliance) with increasing age [13]. It is known that the articulations of the ribs with the sternum and the spinal column may become calcified, and the compliance of the rib articulations decreases with age. The changes in rib articulations may be compounded by the development of kyphosis due to osteoporosis. The decreasing compliance of the chest wall demands more work from the respiratory muscles. For example, in a 70-year-old person, approximately 70% of the total elastic work of breathing is expended on the chest wall, whereas this value is 40% in a 20-year-old.

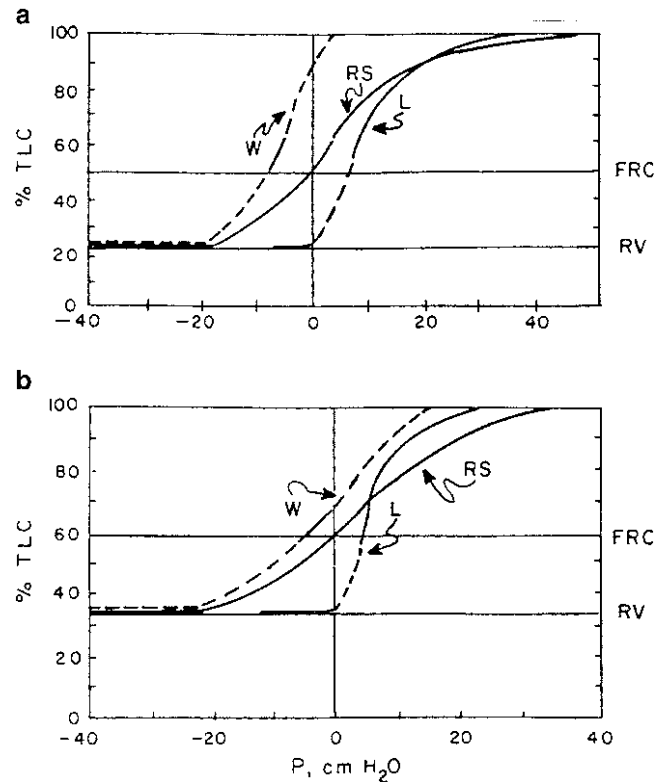

FIGURE 47.4 Static compliance relations of the components of the respiratory system. *L* lungs, *W* chest wall, *RS* total respiratory system, *TLC* total lung capacity, *FRC* functional reserve capacity, *RV* residual volume, *P* pressure gradient, (a) A 20-year-old man; (b) A 60-year-old man. Note that the static compliance of the chest wall is substantially decreased (reduced slope) in the older individual, whereas *FRC* (resting volume of the respiratory system, or the point at which the pressure gradient across the respiratory system is zero) increases somewhat. Note again (compare with Fig. 35.2) that the static recoil pressure of the lungs is reduced in the older subject.

Muscles of Respiration

Age-related changes in nonrespiratory skeletal muscle include decreased work capacity owing to alterations in the efficiency of muscle energy metabolism, atrophy of motor units, and electromyographic abnormalities. Based on lessons learned with other skeletal muscles, it, at first, appeared likely that age-related abnormalities in respiratory muscles would also be found.

An early study by Black and Hyatt [14] appeared to confirm age-related decrements in respiratory muscle function by measuring maximal inspiratory pressure (PI_{max}) and maximal expiratory pressure (PE_{max}) in 120 normal individuals (both smokers and nonsmokers) between the ages 20 and 70. Maximal respiratory pressures in women were 65–70% of those in men. No significant age-related changes were observed in individuals under the age of 55. Trends toward reduced maximal respiratory pressure with age were seen for both sexes and with both PI_{max} and PE_{max} . With the

numbers of men studied, the change with age in PI_{max} was not statistically significant for the male gender.

More recently, McElvaney and coworkers [15] have come to a different conclusion in a similar study of 104 healthy individuals over the age of 55. They found large variation in maximal respiratory pressures from individual to individual (as had Black and Hyatt) but no significant correlation with age. In contrast, in a third population of 160 healthy individuals who ranged in age from 16 to 75 years, Chen and Kuo found significant gender differences in maximal respiratory pressures as well as trends toward decrements with age for both PI_{max} and PE_{max} in both genders [16]. The age-related change in PE_{max} in the male subjects was not statistically significant with the sample size studied. When the 40 individuals of both genders in the youngest age group (16–30 years) were compared with the 40 individuals in the oldest group (61–75 years), the decrement in PI_{max} was 32–36%, and the decrement in PE_{max} was 13–23%. Representative findings for maximal respiratory pressures in women are illustrated in Fig. 47.5.

Chen and Kuo measured inspiratory muscle endurance against a resistive load and found significant decrements with age [16]. Physically active men had greater inspiratory muscle endurance than sedentary men.

In summary, it appears that when populations of healthy individuals of widely differing ages are studied, moderate

FIGURE 47.5 Representative variations in maximal respiratory pressure with age among women. Inspiratory and expiratory measurements were made at residual volume and total lung capacity, respectively. *Open bars*, maximal inspiratory pressure; *hatched bars*, maximal expiratory pressure. *Error bars* are standard errors of the mean. The variations with age were statistically significant but were small in magnitude (from Chen and Kuo [16], with permission).

age-related decrements in respiratory muscle strength and endurance can be found. These studies usually define “healthy” only by the absence of disease and do not control for physical activity. They are complicated by marked inter-individual variability, and longitudinal studies have not been reported. Respiratory muscle function may be better preserved with age than that of other skeletal muscles because of a straining effect of the continuous respiratory muscle activity. Finally, physical activity may have an additional straining effect that enhances inspiratory muscle endurance in all age groups.

Control of Breathing

Stanley and colleagues have found that elderly subjects (mean age 69 years) have a slower, more variable respiratory rate than a young control group [17, 18]. It is doubtful that this isolated observation has any functional significance, but it did suggest that ventilatory control changes with aging.

More important is that ventilation becomes much less responsive to stress in elderly individuals. It is well known that in young individuals sensitive ventilatory control mechanisms match minute ventilation closely to metabolic demands. As a result, arterial blood-gas values remain stable throughout a wide range of activities from rest to strenuous exertion, whereas oxygen consumption and carbon dioxide production vary widely. Similarly, when the efficiency of gas exchange is diminished by a variety of lung problems (e.g., atelectasis and pneumonia) or congestive heart failure, appropriate increases in minute ventilation minimize the potential for resulting hypercapnia or hypoxemia in healthy young individuals.

To compare old and young individuals, ventilatory control mechanisms have typically been tested by inducing either hypoxemia or hypercapnia while monitoring ventilatory parameters. Such tests have shown striking differences between young and elderly individuals in ventilatory and cardiac responses [19–22].

Diminished Ventilatory Response to Hypercapnia

Kronenberg and Drage [21] compared the ventilatory responses to hypercapnia while $PACO_2$ was allowed to rise to 65 mmHg. The elderly individuals had a significantly diminished ventilatory response to hypercapnia, measured as the slope of the relation between ventilation and $PACO_2$.

FIGURE 47.6 Variations in ventilatory responses to hypoxia, with age. Eight normal men aged 64–73 years (mean 69.6 years) (*circles*) were compared to young controls aged 22–30 years (mean 25.6 years) (*squares*). Ventilation was measured while the subjects were exposed to isocapnic progressive hypoxia by a rebreathing method. Values are means \pm SEM. Note that the ventilatory responses were strikingly attenuated in the older individuals (from Kronenberg and Drage [21], with permission).

Diminished Ventilatory Response to Hypoxia

When these same authors [21] measured the ventilatory response to hypoxia, the contrasts between young and aged individuals were even more dramatic (Fig. 47.6). The ventilatory response to PAO₂ 40 mmHg was uniformly smaller in the old subjects, and there was no overlap between the groups. The mean minute ventilation values at PAO₂ 40 mmHg were 40.1 and 10.2 L/min in the young and old groups, respectively.

Diminished Occlusion Pressure Responses

Peterson and Fishman [23] showed that the differences in responses of elderly subjects to both hypercapnia and hypoxia are due to a lesser increase in tidal volume during stress, whereas the ventilatory rate increases normally. These authors also measured airway occlusion pressures, which are valuable indices of respiratory drive that are not affected by either respiratory muscle strength or respiratory mechanics. The measurements, called P₁₀₀, are the negative pressures at the mouth when measured 100 ms after the start of inspiration

FIGURE 47.7 Variations in occlusion pressure responses to hypoxia and hypercapnia, with age. Data are slopes of the relations between occlusion pressure responses and either SaO₂ or end-tidal PCO₂; error bars are the SEM. Occlusion pressure responses are an indicator of ventilatory drive independent of chest wall compliance and respiratory muscle strength. The elderly individuals showed significantly and strikingly diminished ventilatory drives in response to both hypoxia and hypercapnia (from Peterson and Fishman [23], with permission).

against an occluded airway. The occlusion pressure responses to both hypoxia and hypercapnia (Fig. 47.7) were significantly reduced in ten elderly subjects (mean age 73.3 years) when compared to those of nine young control subjects (mean age 24.4 years) [22].

In summary, the compensatory change in tidal volume in response to either hypoxemia or hypercapnia is reduced (often strikingly) with age. The less-effective homeostasis is apparently due to reduced responsiveness of either the ventilatory drive or the neural output from the respiratory center. It has not been determined whether the diminished ventilatory drive results from altered chemoreceptor function or altered function of the respiratory center. Kronenberg and Drage favored altered receptor function based on their observation that elderly subjects responded to an alveolar oxygen tension of 40 mmHg with only an 11% increase in heart rate, whereas the young subjects responded with a 45% increase [21].

Respiratory Load Compensation and Dyspnea

Normally, when there is a change in the mechanical workload of the respiratory system (e.g., with lung disease, changes in posture, or mouth versus nose breathing), there is a reflex

compensation that maintains the ventilation constant. To study the effects of aging, Akiyama and colleagues [24] measured responses to inspiratory flow-resistive loading in young and elderly individuals. In the young control group, inspiratory loading resulted in an increase in P_{100} at each level of induced hypercapnia, such that inspiratory loading did not change the ventilatory response to hypercapnia. In marked contrast, the P_{100} in the elderly group did not change when an inspiratory load was applied. Thus, ventilatory responses to hypercapnia were reduced during inspiratory loading in the elderly group.

At each level of PCO_2 , the intensity of perceived dyspnea in response to inspiratory loading was higher in the elderly than in the control group. Thus, the sensation of dyspnea was intact or enhanced in the elderly subjects, while their compensatory responses were reduced.

Pulmonary Circulation

Pulmonary artery catheterization studies have typically been biased in that only subsets of patients have been reported. The reported studies were performed on individuals who had signs and symptoms that led to referral for heart catheterization. These individuals are probably not representative of “healthy” young and old cohorts. Furthermore, age-related changes in the pulmonary circulation are difficult or impossible to distinguish from changes due to heart disease or age-related changes in cardiac function. Even if they are real, the minor increases in pulmonary vascular resistance and age-related increases in pulmonary artery wedge pressure are probably not physiologically significant.

Pulmonary Function Tests

Several measurements of lung function and exercise capacity decline with age. However, descriptions of “normal” age-related changes are confounded by an increasing prevalence of disease, chronic illness, medication use, and an increasingly sedentary lifestyle. The influences of all of these factors are difficult to distinguish from each other. Superficially, it appears that longitudinal studies would provide the optimal design for distinguishing the effects of age from other influences. Longitudinal studies, however, have methodological problems and biases of their own, the most obvious being that the healthy elderly represent a healthy survival population. Regardless, it does seem that age alone has potentially important effects on lung function.

Lung Volumes

Figure 47.8 illustrates typical lung volume changes with aging based on cross-sectional studies. TLC, the volume of air in the lungs at the end of a maximal inspiration, is marked by the point at which the recoil pressure exerted by the respiratory system is exactly counterbalanced by the PI_{max} generated by the respiratory muscles. Cross-sectional studies of TLC summarized by the European Coal and Steel Community [25, 26], when combined, demonstrated no significant age coefficients for either men or women [25, 26].

Both slow and forced vital capacity (FVC) decline with age more rapidly in men than women. Average decrements in vital capacity per year vary considerably; in cross-sectional studies, declines range from 21 to 33 ml/year in men and 18 to 29 ml/year in women. Ware and colleagues [27], in a study containing both longitudinal and cross-sectional computations, found cross-sectional decreases in FVC for men and women to be -34 and -27.8 ml/year, respectively. Cross-sectional studies of residual volume (RV) and the RV/TLC ratio consistently show increases with age. In the young, RV (the volume of air in the lungs at the end of a maximal expiration) is the volume at which the outward static recoil pressure of the respiratory system is counterbalanced by the maximal pressure exerted by the expiratory muscles. In old subjects, the expiratory flow never completely reaches zero, and RV is determined in part by the length of time an individual can

FIGURE 47.8 Lung volume changes with age. *TLC* total lung capacity, *CC* closing capacity, *FRC* functional residual capacity, *RV* residual volume. Although not labeled, the vital capacity is TLC minus RV . The most consistent age-related changes are an increase in RV and a decrease in ventilatory capacity (from Peterson and Fishman [23], with permission).

maintain the expiratory effort. Other factors leading to an increased RV with aging include loss of lung recoil, decreased chest wall compliance, decreased expiratory muscle force, and increased small airway closure (air trapping) in dependent lung zones [6].

FRC is also determined by the balance of the elastic recoil forces of the lung and chest wall, but in this instance, the equilibrium occurs at the end of a quiet (unforced) exhalation. Because lung recoil decreases and the chest wall stiffens with age, one would expect the FRC to increase. Cross-sectional studies, however, show inconsistent results, with most showing no change in FRC with aging. Studies that do find an increase in FRC with aging show a small positive age coefficient on the order of 7–16 ml/year. McClaran et al.'s longitudinal study found the FRC to increase 40 ml/year, but again the change was not significant [28]. Despite the conflicting data, it is generally believed that FRC increases somewhat with aging.

Loss of lung recoil also changes the volume at which airway closure occurs. When adults exhale fully, small airways close in the region of the terminal bronchioles in dependent lung zones. The lung volume at which this closure begins is measured as the closing volume or, if it is added to the residual volume, closing capacity. Closing volume increases linearly with age from about 5–10% of TLC at age 20 to about 30% of TLC at age 70. The loss of lung elastic recoil, a possible decrease in the recoil of the intrapulmonary airways, and decreases in small airway diameter probably explain most of the change in closing volume.

On average, closing volume encroaches on tidal volume by about age 44 when subjects are supine and at about age 65 when they are seated (Fig. 47.8). Airway closure during tidal breathing explains part of the decrease in arterial oxygen tension observed with aging.

Airflow

Although essentially all expiratory flows measured during a maximum expiratory maneuver decrease with age, the declines are most evident at low lung volumes (Fig. 47.9). Nunn and Dregg [29], in a study of 225 male and 228 healthy female nonsmokers, reported a modest decrease in peak expiratory flow (PEF) with aging. The rate of decline in FVC and forced expiratory volume at 1 s (FEV_1) with age tends to be more in (1) men, (2) tall individuals, (3) individuals with large baseline values, and (4) individuals with increased airway reactivity. Total airway resistance, measured at FRC, does not change with aging.

FIGURE 47.9 Maximal flow-volume curves, showing the changes in expiratory flow rates with age. Data are for elderly women (mean age 63 years) and control young women (mean age 25 years). Although all flows tend to be reduced with aging, the reduction in flow is most evident at lower lung volumes, where the flow-volume curve is concave in regard to the volume axis (from Peterson and Fishman [23], with permission).

Gas Exchange

The carbon monoxide diffusing capacity (DL_{CO}) declines with age. Early cross-sectional studies reported a linear decline in DL_{CO} of about -0.1 ml CO/min/mmHg/year for men and -0.15 ml/min/mmHg/year for women [30, 31]. These declines are roughly 0.5% per year. In a large representative sample of US adult men, Neas and Schwartz [32] found an almost identical linear fall in DL_{CO} . In women, however, they found a nonlinear, quadratic decline in DL_{CO} with age. After age 47, the nonlinear component was not significant, and the decline in DL_{CO} was identical to that in the earlier studies. The decline in DL_{CO} with age did not vary with race.

The decline in DL_{CO} with age is not explained by increased nonhomogeneity of gas distribution. Measured DL_{CO} decreases as the alveolar PO_2 increases and the venous hemoglobin concentration falls. Neither alveolar PO_2 nor hemoglobin concentration varies enough with age to explain the aging-related decline in DL_{CO} . The magnitude of the decline in DL_{CO} corresponds fairly well to the magnitude of the known aging-related decrease in the internal surface area of the lung.

Although alveolar oxygen pressure (PAO_2) remains constant with age, arterial PO_2 decreases, and the alveolar-arterial oxygen tension gradient ($PA-aO_2$) increases with

FIGURE 47.10 Decreasing arterial oxygen tension (PO_2) with age. The lack of change in alveolar oxygen tension is also shown for comparison with PaO_2 . The widening alveolar–arterial partial pressure difference for oxygen results from the development of basilar areas of low ventilation/perfusion ratios due to airway closure in the elderly (modified from Sorbini et al. [33], with permission).

aging (Fig. 47.10). The decline in PaO_2 with aging is more pronounced when subjects are studied in a recumbent as contrasted with an upright position. The most likely explanation for the decline in PaO_2 with aging is increased mismatching of ventilation to blood flow (V/Q) as airway closure begins to occur during tidal breathing.

Summary and Implications for Geriatric Surgery

Aging is accompanied by readily measurable changes in respiratory system mechanics, gas exchange, ventilatory control, and respiratory muscle strength. Despite these changes, the activities of normal elderly individuals are not limited because they have substantial functional reserve of the respiratory system early in their lives. When anticipating operative morbidity and potential operative complications, however, the surgeon must be aware that elderly patients have lost much, or all, of their respiratory reserve. Operative stresses, pain, and bed rest are always less well tolerated by the respiratory system of elderly patients.

Changes in ventilatory control among geriatric patients deserve special attention. Because of changes in chemoreceptor function and respiratory center function, elderly individuals respond differently to hypoxemia and hypercapnia than their younger counterparts. Thus, an elderly patient who is developing respiratory failure may appear comfortable and may not be tachypneic or tachycardic. Vigilance and awareness on the part of the health-care team allow detection of respiratory complications early, through measurement of oxygen saturation and arterial blood gases. Such vigilance allows appropriate *nonemergent* interventions.

Chapter 48

Pulmonary Surgery for Malignant Disease in the Elderly

Sarah E. Billmeier and Michael T. Jaklitsch

CASE STUDY

Ms. Jones is an 82-year-old F who was in her usual state of good health when she developed a fever and cough. A chest X-ray revealed left upper lobe pneumonia and she was successfully treated with a course of antibiotics. Three months later her pneumonia recurred, and at that time a chest CT showed a left upper lobe nodule. A biopsy of the nodule was consistent with adenocarcinoma, and she was referred for thoracic surgery evaluation.

On evaluation Ms. Jones is found to be healthy and active, despite recent flares of arthritis in her hands. Her family refers to her as “well preserved.” She walks daily for a quarter mile with her family, shops for her own groceries and enjoys gardening. She carries a basket of laundry up two flights of stairs every day, and carries two bags of groceries at a time into the kitchen

from her car. She had a myocardial infarction 17 years ago and 2 years ago had a cardiac stent placed. She has a history of reflux disease which seems to be worsening over the past year. She has osteoarthritis and the kyphosis in her back has become quite obvious. She has a distant 27-pack year smoking history. She has extensive social supports and is viewed as the matriarch of a family that includes 6 children and 21 grandchildren. Her first great grandchild is expected this fall. She is active in her church and volunteers at a shelter serving meals once a month.

Pulmonary function tests are notable for good lung function with an FEV1 of 1.8 L (81% predicted) and an FVC of 2.6 L (88% predicted). She is able to walk 1,400 feet in 6 min without hypoxia. She is able to climb two flights of stairs without difficulty. A brain MRI, bronchoscopy, and mediastinoscopy are all negative. How does Ms. Jones advanced age affect her management?

Introduction

With the aging of the baby boomer population, the number of people in the USA over 65 is expected to nearly double by 2040. Currently 12.5% of the US population is over the age of 65, and this percentage is projected to increase to 20% by the year 2050. The average life expectancy in the USA is 77.8 and projected to increase to over 80 by 2050 [1–4].

Older patients increasingly present for consideration of thoracic surgery, and determining the optimal management for this group of patients will be a more frequent challenge in the future. While elderly patients present with a spectrum of thoracic disease, both benign and malignant, patients with

cancer comprise the largest and most studied subset of this population.

Lung cancer is a disease of the elderly. The median age of diagnosis for lung cancer in the USA is 71 years and over 65% of patients are diagnosed after age 65. National Cancer Institute statistics indicate that lung cancer is the leading cause of cancer mortality in men and women [5, 6]. In 2008 an estimated 215,020 Americans will be diagnosed and 161,840 people will die of lung cancer. Over 100,000 lung cancer deaths will be in patients over the age of 65 [7].

Non-small cell lung cancer (NSCLC) comprises 80–85% of primary lung tumors, small cell lung cancer (SCLC) makes up 15–20% and 1–2% are pulmonary carcinoid [8–10]. SCLC is usually widely metastatic at time of diagnosis, and rarely under the purview of the surgeon; however, the percentage of lung cancer patients with SCLC histology falls with age [10]. Surgical resection of NSCLC and pulmonary carcinoid offers the best chance for oncologic cure. Additionally, retrospective

S.E. Billmeier (✉)
General Surgery, Brigham and Women’s Hospital, Boston, MA, USA
e-mail: sbillmeier@partners.org

evidence suggests that resection of isolated metastases to the lung may improve survival.

The decision to undergo surgical resection for malignant disease should not be based on age alone. An understanding of the unique qualities of this patient population has led to improved surgical outcomes for the elderly over the last several decades. Patient evaluation, selection, and peri-operative management must all be adapted to provide best possible care for the increasing numbers of aged patients undergoing surgery for cancer. Management of an elderly lung cancer patient requires a global consideration of the characteristics of aging, differences in tumor presentation and histology, and co-morbidities that tend to accumulate over time. The initial interview with a patient and family members is used to elucidate important variables that may impact operative risk and expectations of the recovery process. These questions should elucidate the current independent status of the patient, social supports, mood, and signs of reduced activity or physical limitations. After all, the elderly population is a heterogeneous group of patients ranging in functional reserve from the surprisingly well preserved to the wheelchair bound.

Physiologic Changes of Age

Physiologic changes of the respiratory system associated with aging include reduced chest wall compliance with stiffening of calcified costal cartilages and narrowing of the intervertebral disc space. A progressively restricted ribcage is accompanied by decreased diaphragmatic excursion. Postoperative weakness of the hemi-diaphragm in this group can lead to otherwise unexplained respiratory failure. There is a reduction of lung elastic recoil with loss of alveolar architecture producing a decreased alveolar gas exchange surface. The loss of lung elastic recoil and decreased lung compliance diminishes negative intrapleural pressure, which then prevents reopening of the small airways, resulting in air trapping and inadequate ventilation. Functionally this manifests in a gradual decline of vital capacity and partial pressure of oxygen (P_{O_2}), with an increase in residual volume. Progressive atrophy creates weakness of the respiratory musculature. Decline in motor power of the accessory muscles and a stiffening of the chest wall also result in a declining forced expiratory volume in 1 s (FEV1). Changes in lung compliance are not uniformly distributed. Higher respiratory rates therefore increase ventilation-perfusion mismatch. Additionally, there is a decrease in central nervous system responsiveness. The elderly exhibit a blunted ventilatory response to both hypoxic and hypercapnic insults [11, 12].

Physiologic changes in lung mechanics make elderly patients particularly sensitive to narcotics and muscle relaxants, as well as to supine positioning. Elderly patients are also at increased risk for respiratory tract infections, due to

waning immune responses [13]. Smoking in particular has been shown to cause bronchial mucociliary dysfunction [14], which has been associated with increased susceptibility to infection [15]. Finally, elderly patients with marked kyphosis and accompanying paraesophageal diaphragmatic hernias are at particular risk for postoperative aspiration.

Increasing age is associated with declines in other organ systems as well. There is a decline in glomerular filtration rate, an increasing incidence of heart disease, and an increasing incidence of cognitive dysfunction. Changes in body composition decrease the volume of distribution of water-soluble drugs [16]. Additionally, elderly patients take more medications than younger patients and are vulnerable to adverse drug effects.

Preoperative Evaluation

Elderly patients are at increased risk for preoperative morbidity and mortality due to both decreased ability to recover physiologic homeostasis after surgical stress and co-morbid conditions. Older patients represent a heterogeneous population, and should be offered surgery based on physiologic rather than chronological age. A thorough preoperative assessment is imperative to determine whether a patient is an appropriate surgical candidate and to predict and avoid postoperative complications. Numerous risk assessment tools have been created to define preoperative variables that correlate with poor outcomes; however, an easy to use, strongly predictive tool, has been elusive. Geriatric assessment tools aimed at predicting outcomes in the specific elderly surgical population remain under study.

All patients in consideration for lung cancer resection surgery require a complete history and physical exam with particular attention to characterization of symptoms, smoking history, and weight loss. At a minimum, patients should undergo a chest X-ray, electrocardiogram, a room air arterial blood gas, pulmonary function tests for patients undergoing lung resection, basic laboratory work, and a complete staging evaluation. Further workup can be determined based on symptoms or the status of co-morbid conditions.

Accurate diagnosis and staging is of utmost importance to ensure that patients are appropriately chosen for operative resection. Elderly patients should have radiographic and surgical staging of suspected lung cancers in the same manner as younger counterparts. Only after the exact stage is known can rational treatment decisions be made. Therefore, elderly patients should have chest CT scans to image suspected lung nodules, PET scans to look for metastatic disease, brain scans to look for occult metastases and, if indicated, cervical mediastinoscopy to stage mediastinal nodes. Elderly patients with suspected lung nodules should not be denied this standard workup unless their functional status is so impaired that treatment is not possible.

Cardiac Risk Assessment

The American Heart Association (AHA) and American College of Cardiology (ACC) developed consensus practice guideline for peri-operative cardiovascular evaluation for non-cardiac surgery that provides a template for assessing patients of all ages [17]. The AHA/ACC guidelines describe a step-wise approach to preoperative surgery with risk stratification and further imaging determined by utilizing symptoms, clinical predictors, and functional capacity. Clinical history should focus on assessment for coronary risk factors and physical capacity including the ability to climb two flights of stairs or walk one block. In general, patients with poor functional status, or patients with a history of angina or claudication should undergo noninvasive testing. In thoracic surgery patients it may be difficult to determine if symptom etiology is the result of cardiac or pulmonary pathology, thus it is appropriate to have a low threshold for additional cardiac imaging and assessment by a cardiologist to assist with risk stratification.

Supraventricular tachycardias are very common after thoracic surgery, with increased risk for older patients or those with a faster preoperative heart rate [18]. The risk of postoperative atrial fibrillation is 19% in patients undergoing lung resection for cancer [19]. Randomized trials of thoracic surgery patients have determined that calcium channel blockers or beta-blockers can reduce the incidence of postoperative atrial fibrillation by 50–60%; however, beta-blockers were associated with an increased risk of pulmonary edema. Neither class of medication reduced mortality. Three trials showed that digitalis increased the risk of atrial arrhythmias [20]. Beta-blockers and calcium channel blockers will both reduce postoperative atrial fibrillation; however, beta-blockers are preferred by some due to their broader benefits of cardiac risk reduction. On the other hand, up to half the doses of postoperative beta-blocker may have to be held due to transient hypotension or bradycardia, leading others to recommend the use of calcium channel blockers.

Pulmonary Risk Assessment

All patients under consideration for lung resection surgery should have pulmonary function tests performed. FEV1 by spirometry is the most common measured value used to determine a patient's suitability for surgery. In the 1970s, data obtained from over 2,000 patients showed a <5% mortality rate for patients with an FEV1 >1.5 L for lobectomy and >2 L for pneumonectomy [21, 22]. Absolute values for FEV1 may create a bias against older people; however, a value of >80% of predicted has been quoted by some as sufficient for a patient to undergo pneumonectomy without further pulmonary testing [23]. In reviewing more recent spirometry studies performed from NSCLC patients in 1994–2000, Datta and

Lahiri concluded that increased postoperative morbidity and mortality were predicted by an FEV1 of <2 L or <60% predicted for pneumonectomy, an FEV1 of <1.6 L for lobectomy, and <0.6 L for wedge or segmentectomy [24].

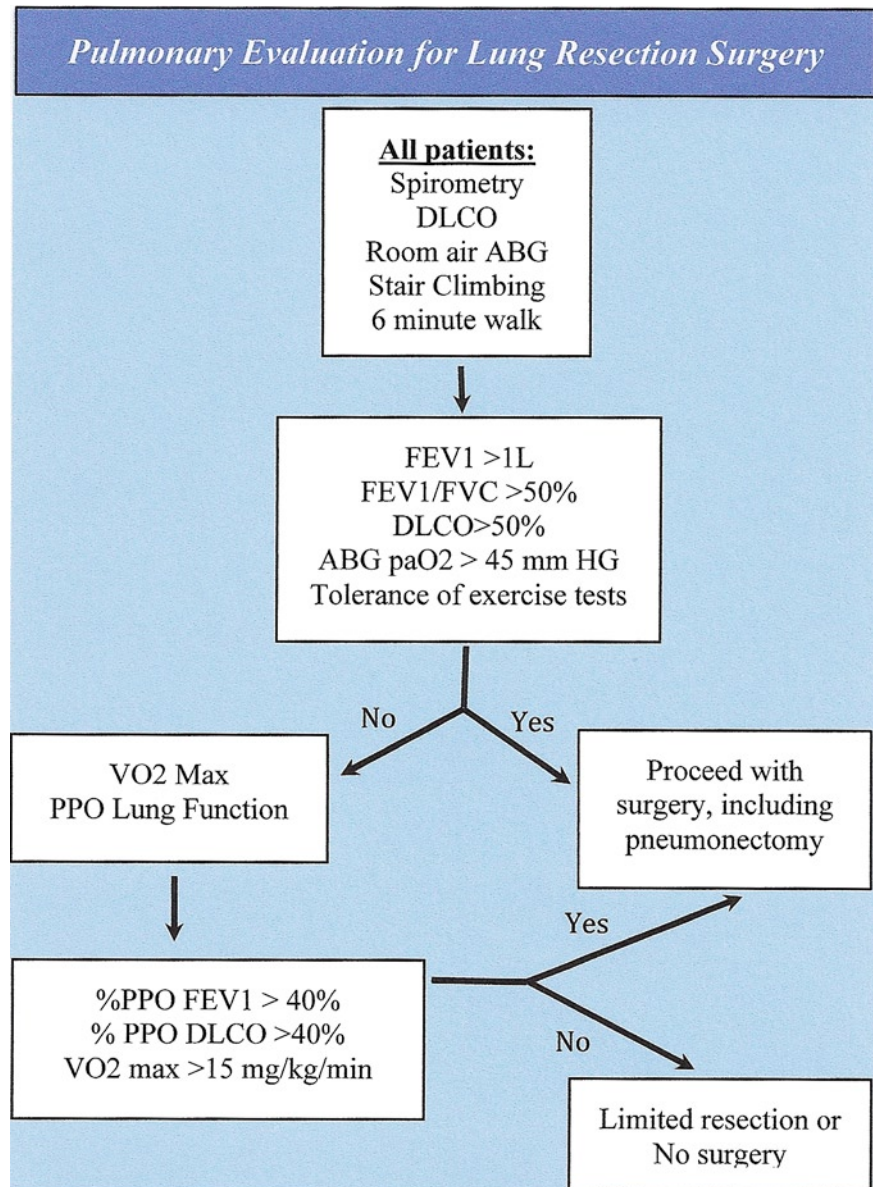

Lung resections have been undertaken in patients with much poorer lung function. In 2005, Linden et al. published data from a series of 100 consecutive patients with preoperative FEV1 of <35% predicted undergoing lung tumor resection. In this series, there was a 1% mortality rate (single case of perforated colonic diverticulum) and a 36% complication rate. Morbidity was dominated by 22% of patients with prolonged air leaks. Eleven patients were discharged with a new oxygen requirement, and four patients developed pneumonia. Only one patient was discharged on a ventilator and three other patients required intubation for >48 h [25].

In a study of 237 patients, Ferguson et al. found preoperative diffusion capacity for carbon monoxide (DLCO) to be more predictive of postoperative mortality than FEV1. In this study, a DLCO of <60% predicted was associated with increased mortality and a DLCO of <80% predicted was predictive of increased pulmonary complications [26]. Other studies, however, have not found this parameter to be a significant predictor of postoperative complications [27, 28]. DLCO and spirometry may be used as complimentary tests, particularly in patients with diffuse parenchymal disease or dyspnea that is out of proportion to the FEV1, with a low DLCO prompting further evaluation [22].

Formal and simple exercise testing evaluates the cardio-pulmonary system under induced physiological stress and also has been found to be predictive of postoperative complications. Girish et al. prospectively studied symptom-limited stair climbing in thoracic and upper abdominal surgery patients. No complications occurred in patients who could climb seven flights of stairs, while 89% of patients unable to climb one flight of stairs had complications. Inability to climb two flights of stairs had a positive predictive value of 80%. The ability of patients to climb stairs was found to be inversely related to the length of postoperative hospital stay [29]. The 6-min walk test (6MWT) measures the distanced walked over a period of 6 min. A normal patient is able to cover at least 1,400 feet in 6 min. In a qualitative review, Solway concluded that the 6MWT was easy to administer and more reflective of activities of daily living than other walk tests [30]. While stair climbing and 6MWT are easy to perform, their use in elderly patients may be limited by orthopedic impairments, peripheral vascular insufficiency or neurological impairments.

As published previously [31], a recommended preoperative pulmonary evaluation for an elderly patient should consist of spirometry, pulmonary diffusion capacity of the lung for carbon monoxide (DLCO), room air ABG, and exercise tolerance tests including stair climbing and 6-min walk. Patients with an FEV1 >1 L and no major abnormality of other tests (FEV1/FVC >50%, DLCO >50% predicted, ABG paO_2 >45 mm Hg, tolerance of exercise tests) may

FIGURE 48.1 Recommended pulmonary evaluation for patients undergoing lung resection surgery. *DLCO* diffusion capacity for carbon monoxide, *ABG* arterial blood gas, *FEV1* forced expiratory volume in 1 s, *FVC* forced vital capacity, *VO₂ Max* maximal oxygen consumption, *PPO* predicted postoperative.

safely proceed with surgery, including pneumonectomy (Fig. 48.1).

Further evaluation for patients who fall outside these criteria include ventilation/perfusion scans to calculate predicted postoperative (PPO) lung function and VO_2 max testing. A PPO FEV1 threshold of 0.8 L [32] or 0.7 L [33] has been suggested as a lower limit value for proceeding with lung resection. Absolute values of PPO FEV1 can underestimate postoperative lung function in people with small stature or the elderly, and can thus be converted into percent-predicted postoperative (% PPO) lung function. Multiple studies have suggested that morbidity increases at a

threshold % PPO FEV1 of <40%, or a % PPO DLCO of <40% [26, 34–37].

Measurement of maximal oxygen consumption (VO_2 max) by formal cardiopulmonary exercise testing is helpful to further risk stratify patients with borderline lung function. A VO_2 max of <10 ml/kg/min had a very high operative morbidity (26% total in combined data) in several small case series. VO_2 max values of 10–15 ml/kg/min had an intermediate peri-operative morbidity (8.3% total) whereas patients with >15 mg/kg/min can proceed with lung resection surgery with an acceptable mortality rate [22].

Cognitive Assessment

The likelihood of returning to baseline physical and mental function after surgery is one of the most important outcomes for an elderly patient. While patients and their families accept that there will be a postoperative recovery time in the hospital or rehabilitation setting, it is difficult to assess the magnitude of this functional decline and predict the risk of permanent loss of independence. There is a paucity of data assessing changes in quality of life after thoracic surgery in the elderly, and few studies that assess whether surgery triggers postoperative loss of independence, or change in need for assistance or living requirements. A study of 68 octogenarians undergoing pulmonary resections at Johns Hopkins Medical Institutions showed that 80% of patients were discharged directly to home from the hospital rather than to rehab, offering some proxy information regarding immediate postoperative return to function [38]. Moller et al. published a study in 1998 that showed a 25% rate of cognitive dysfunction at 1 week postop from major noncardiac surgery in elderly patients (average age 68), with continued dysfunction in 9% at 3 months [39]. Data from many studies verify a high incidence of postoperative cognitive dysfunction in the first week after surgery, and dysfunction does tend to increase with age. Only one other study has substantiated long-term declines over controls, and some have suggested that declines found in these studies may be due to random variation [40, 41]. Karneko et al. determined that preoperative dementia was a risk factor for postoperative delirium [42]. Furthermore, Fukuse et al. found that thoracic surgery patients with preoperative dementia, as estimated by the mini-mental status exam (MMS), were fourfold more likely to have postoperative complications [43].

Geriatric Assessments

There are multiple assessment indices that have been applied to elderly patients to link preoperative function with risk for poor outcome. Functional status describes the ability to perform self-care, self-maintenance, and physical activities. Traditional measures used to assess functional status are activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs are six basic self-care skills, including the ability to bathe, dress, go to the toilet, transfer from a bed to chair, maintain continence, and feed one's self. IADLs include higher functioning skills that are used to maintain independence in the community. This scale assesses ability to use the telephone, go shopping, prepare food, perform housekeeping and laundry, use various modes of transportation, assume responsibility for medications, and

the ability to handle finances. Need for assistance in these tasks has been predictive of prolonged hospital stay, nursing home placement and home-care requirements [44, 45]. Poor nutritional status, defined as a BMI <22 kg/m² has been associated with increased need for assistance with ADLs and a decreased 1-year survival [46]. A lower ADL score is associated with postoperative complications [47]. The information source reporting a patient's functional status biases the results, with self-reported scores rating higher than scores reported by a significant other or nurse [48].

Performance status is a standardized scale designed to measure the ability of a cancer patient to perform ordinary tasks. There are two scales, the Karnofsky performance scale, which ranges from 0 (dead) to 100 (normal) and the ECOG scale that ranges from 0 (asymptomatic) to 5 (dead). Comparisons of the two scales have been validated with a large sample of patients [49]. Performance status has been used to select patients for entry into chemotherapy trials; however, it is also well accepted to be associated with postoperative morbidity [50–52].

Postoperative Care

Postoperative management must be optimized specifically for the elderly population. Narcotic use should be minimized whenever possible to prevent delirium, and appropriate elderly patients should be assessed for preoperative placement of a thoracic epidural catheter for analgesia. Benzodiazapines and medications for sleep should also be minimized. Excellent pulmonary hygiene must be maintained with frequent chest physiotherapy and early ambulation. At our institution, thoracic ambulation carts, as shown in Fig. 48.2, are used to facilitate walking patients who require oxygen, and are otherwise tethered with multiple lines and catheters. Forearms are supported by pads while hands wrap around a handbrake. Oxygen tanks and ambulatory saturation monitors are stored along the sides. Pleural drainage systems can be suspended from the side rails. A cloth strap is used to secure the patient to the cart during ambulation.

Non-small Cell Lung Cancer

Stage at Presentation

Elderly patients more frequently have early-stage disease, compared to younger patients with lung cancer. O'Rourke et al. used a database of 22,874 patients to demonstrate that percentage of patients with surgically resectable disease at

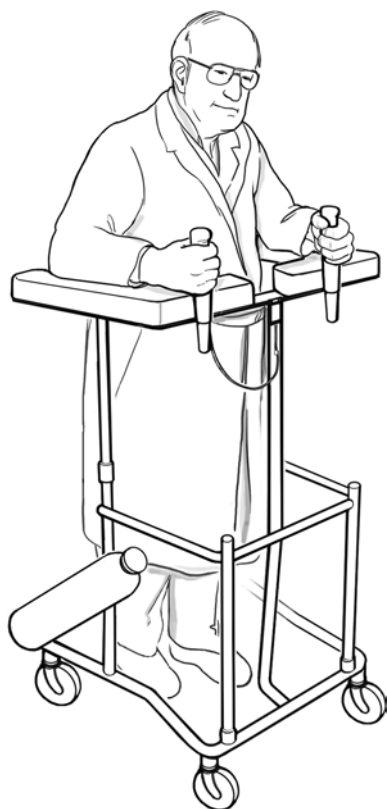

FIGURE 48.2 Thoracic ambulation cart used to facilitate early postoperative ambulation (artwork by Marcia Williams).

diagnosis increases with age. The percent of lung cancer patients with local stage NSCLC increased from 15.3% of those aged 54 years or younger, to 19.2% of those aged 55–64 years, to 21.9% of those aged 65–74 years, and to 25.4% of those aged 75 years or older [53]. Data published from the Surveillance, epidemiology, and end results (SEER) database in 2005 analyzing a cohort of 14,555 patients with early-stage NSCLC showed that the frequency of stage I disease increased from 79% in patients <65 to 87% in patients age 75 or greater [54]. Thus, although the elderly are at higher risk of developing lung cancer, a higher proportion present with potentially curable disease.

Histology

Elderly patients are more likely to be diagnosed with squamous cell carcinoma (SCC) over other histology types [10, 55, 56]. Mery et al.'s analysis of the SEER database showed that the frequency of SCC increased from 27% in patients <65 years old, to 38% in patients 75 and older, with parallel decreases in frequency of adenocarcinoma from 61 to 50% in corresponding age groups [54]. SCCs are associated with a higher incidence of local disease [53], tend to

have lower recurrence rates and may have longer survival times than non-squamous cell cancers [57–59]. Squamous cell tumors are more likely to be centrally located however, and thus are more likely to require pneumonectomy for curative resection.

Extent of Resection

Surgical resection for NSCLC offers the best chance for cure. The extent of NSCLC resection in elderly patients has been extensively debated, with advocates for limited resections for the aged. Lobectomy, removal of one of the five lobes of the lung and associated lymph nodes within a single pleural membrane, is considered standard of care for surgical resection of early-stage NSCLC [60]. Unfortunately there are multiple studies that substantiate age as a risk factor for death after thoracotomy. Using data from the 1960s and 1970s, several small single institution studies published operative mortality rates of 14–27% for the elderly depending on age and type of surgery [61–64]. These findings were confirmed by a multiinstitution study by the Lung Cancer Study Group in 1983. Ginsberg et al. reviewed 2,200 cases of lung resection for cancer and found that operative mortality increased proportionally with age. Patients with age <60 had a 1.3% 30-day mortality rate, with increasing rates of 4.1, 7.0, and 8.1% mortality rates for the 60–69, 70–79, and 80 or greater age groups, respectively [65].

More recently, Mery et al. determined a 30-day postoperative mortality rate of 14,555 patients who had undergone curative resections for treating stage I or II NSCLC over the period of 1992–1997. In an analysis of patients undergoing all types of surgery, there was a 0.45% mortality rate for those under age 65 years old, 0.6% for ages 65–74, and 1.2% for patients age 75 or older ($p=0.001$). Mortality differences were found to be primarily due to differences in survival of patient undergoing lobectomy, with 0.3, 0.5, and 1.5% mortality, respectively, for these corresponding age groups ($p=0.0001$). The difference in peri-operative mortality was statistically similar for patients undergoing limited resection [66]. Prior published reports likewise did not identify a difference in expected operative mortality after thoracotomy if lung-sparing operations were performed [67–69].

The American College of Surgeons Oncology Group (ACOSOG) Z0030 Study published morbidity and mortality data in 2006 for 1,023 clinically resectable T1 or T2, N0 or non-hilar N1 NSCLC patients randomized over a period from 1999 to 2004 to undergo pulmonary resection with lymph node sampling vs. mediastinal lymph node dissection. Their age-stratified morbidity and mortality data is shown in Table 48.1. Notably, overall mortality was 1.4%, improved from Ginsberg's reported 3.8%, and was not statistically associated with age [70]. Ninety percent of patients in

TABLE 48.1 ACOSOG Z0030 Study age-stratified morbidity and mortality after resection for clinically resectable T1 or T2, N0 or non-hilar N1 NSCLC

Event	Age <50 (n=35)	50–59 (n=171)	60–69 (n=386)	70–79 (n=361)	80+ (n=70)
One or more complications	8 (23%)	50 (29%)	136 (35%)	162 (45%)	34 (49%)
Air leak >7 days	1 (3%)	14 (8%)	24 (6%)	33 (9%)	6 (9%)
Chest tube drainage >7 days	0	14 (8%)	42 (11%)	53 (15%)	9 (13%)
Chylothorax	1 (3%)	3 (2%)	3 (1%)	5 (1%)	1 (1%)
Hemorrhage	1 (3%)	3 (2%)	10 (3%)	16 (4%)	4 (6%)

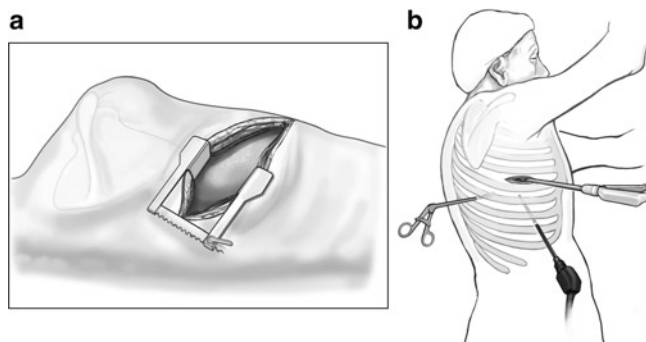

FIGURE 48.3 Lung resection surgery via (a) posteriolateral thoracotomy (b) video-assisted thoracoscopic surgery (artwork by Marcia Williams).

the ACOSOG Z0030 study underwent resection via a thoracotomy, with the remaining procedures performed as video-assisted thoracic surgery (VATS) or VATS-assisted resections. Operative mortality reported by Ginsberg for pneumonectomy and lobectomy was 6.2 and 2.9%, respectively, compared with 0 and 1.3%, in the ACOSOG study. Notably the pneumonectomy rate of the earlier study was 25.6 vs. 4% in ACOSOG, likely partially explaining the higher mortality rate of the earlier study. The complication rate did rise as age increased, with 49% of patients in the 80 and over age group experiencing one or more complication.

The operative risk of death after pulmonary resections is largely attributable to two anatomical disruptions. First there is the loss of functional lung tissue, and secondly there is the morbidity and mortality introduced by the access thoracotomy. Operative strategies particular to the elderly population addresses both of these fronts, with use of video-assisted thoracoscopic surgery (VATS) to minimize the chest wall disruption of a thoracotomy and by consideration of limited resections for the most elderly. Figure 48.3 illustrates the difference in the disruption of chest wall musculature between thoracotomy and VATS approaches.

VATS is defined as surgery performed through two or three incisions that are 2 cm in length. A utility incision <10 cm long may be used, without spreading of the ribs.

VATS procedures in the elderly have been shown to have lower morbidity, lower rates of postoperative delirium and result in earlier ambulation, a lower narcotic requirement, and a quicker recovery time [71–75].

Limited resections, consisting of either a segmentectomy or wedge resection, remove less lung tissue and are usually performed via VATS. These operations are associated with less peri-operative morbidity and mortality; however, do not completely remove draining lymphatics and may be associated with poorer oncologic outcomes. A randomized trial by the Lung Cancer Study Group of limited resection vs. lobectomy for T1 N0 disease revealed a tripling of locoregional recurrence with limited resection, and a trend toward improved survival in the lobectomy group [76]. Divergence of the survival curves between lobectomy and limited resection did not occur until 3 years after surgery, however, indicating a potential role for limited resection in patients with a shorter expected life span. Additional studies have concluded that limited resection remains a “compromise” treatment for elderly patients or those with limited cardiopulmonary reserve [77]. An age-stratified analysis of 14,555 patients in the SEER database, showed no benefit for lobectomy over limited resection in patients over age 71 [54]. Figure 48.4 shows a schematic of the range of lung resections. The decision to perform a limited resection vs. a lobectomy must take into account the patient’s ability to tolerate a larger surgery and potential associated complications vs. a smaller resection with less durable oncologic outcomes.

Pulmonary Carcinoid

Pulmonary carcinoids represent 1–2% of lung tumors. They consist of a spectrum of neuroendocrine tumors that are divided into those with typical (TC) or atypical (AC) histological features. While carcinoids tend to present in younger patients, atypical tumors are often diagnosed about 10 years later than typical carcinoid, occurring in the sixth decade.

FIGURE 48.4 Extent of resection, (a) wedge resection, (b) lobectomy, (c) and pneumonectomy (artwork by Marcia Williams).

Atypical carcinoids tend to be larger, are usually localized to the peripheral lung fields, and are more aggressive than typical carcinoids. The 5-year survival is 40–60 vs. 90% for indolent typical carcinoids [78]. Limited resection with wedge or segmentectomy is the preferred treatment for localized carcinoids. More extensive resection has been advocated for atypical carcinoids, with extent of resection mirroring recommendations for NSCLC [79, 80].

Surgical Resection for Pulmonary Metastases

Metastasis to the lungs is a common oncologic problem. Pulmonary metastases tend to be an indicator of widely metastatic disease; however, in some patients metastases to the lungs may occur in isolation. Retrospective evidence suggests that highly selected patients may have improved survival after resection of pulmonary metastases. Indications for the procedure include (1) control of the primary site, (2) metastatic disease isolated to the thorax, (3) resectable disease, and (4) sufficient cardiopulmonary reserve for the operation [81]. Most studies have found that age does not have a prognostic influence on overall survival [82–87].

The largest evaluation of outcomes after lung metastasectomy comes from the International Registry of Lung Metastases. Established in 1990, the registry enrolls all patients who have undergone resection of lung metastases with curative intent. Of the 5,206 patients enrolled between 1991 and 1995, 43% of lung metastases were epithelial in origin, 42% were sarcomas, 7% were germ cell tumors, 6% were melanomas, and 2% were other types. Single metastases accounted for 46% and multiple metastases 52%. Germ cell tumors had the best survival and melanoma the poorest survival at 5 and 10 years (68% at 5 years and 63% at 10 years vs. 21 and 14%, respectively). The survival rates for epithelial

tumors and sarcomas did not differ significantly (37% at 5 years and 21% at 10 years vs. 31 and 26%, respectively). Rates of recurrence also varied by histology type, with 64% for sarcomas and melanoma, 46% for epithelial and 26% for germ cell tumors with a median time to recurrence of 10 months. In a multivariate analysis, disease-free interval (DFI), number of metastases and tumor type were highly prognostic of long-term survival. Based on these findings, Pastorino et al. proposed four prognostic groupings to provide a framework for management. Group I consisted of patients with resectable metastases, a DFI ≥ 36 months and a single metastasis. Group II patients had resectable metastases, and a DFI of <36 months or multiple metastases. Group III again had resectable lesions and both a DFI of <36 months and multiple metastases. Patients with unresectable metastases made up group IV. Median survival for these four groups were 61, 34, 24, and 14 months for groups I–IV, respectively [87].

The use of VATS over thoracotomy for lung metastasectomy is controversial, as the surgeon is not able to palpate the lung for additional lesions. In 1994, Collie et al. reported that conventional CT missed up to 50% of pulmonary metastases found at surgery [88]. Furthermore, McCormack et al. found additional malignant lesions at thoracotomy in 56% of patients after initial VATS exploration, and thus concluded that thoracotomy with manual palpation was the gold standard for metastasectomy [89]. Preoperative evaluation with PET has a reported sensitivity of up to 94% for lesions 1.1–1.9 cm; however, it has limited ability to detect smaller lesions [90]. Other investigators, however, found no difference in rates of recurrence or survival between VATS and thoracotomy [91, 92]. As advances in imaging technology increase the ability to detect smaller lesions, it is likely that the use of VATS will become more commonplace, particularly in older patients. Elderly patients with isolated pulmonary metastases and adequate cardiopulmonary reserve should be considered for surgical resection.

CASE STUDY UPDATE

Given Ms. Jones' relatively good health and performance status, her expected life expectancy was felt to be at least 5 years, and that this would be shortened without resection of her cancer. As an octogenarian, a limited VATS resection was chosen over thoracotomy to reduce perioperative morbidity and mortality. She underwent a VATS left upper lobe wedge resection and mediastinal nodal sampling without event, and was discharged home on postoperative day 4. Her pathology returned as T1 N0 Mx bronchioalveolar carcinoma (BAC). Ms. Jones continued to do well until 18 months after her surgery when a new contralateral right upper lobe spiculated mass was detected on follow-up chest CT scan. Interval follow-up CT showed slow growth of this nodule and a lack of

lymphadenopathy. A bone scan and head CT was negative for metastatic disease. Diagnostically, it was unclear if this was a metastasis, a new primary tumor, or a benign nodule. She otherwise remained in good health and elected to proceed with VATS wedge resection of this second nodule. Pathology from this resection again proved to be BAC.

Two years after her second resection her chest CT showed evidence of recurrence of BAC, now in the left lower lobe, and she developed a left pulmonary effusion. She began to have progressive shortness of breath and was started on gefitinib. This stabilized her disease and her symptoms for another 12 months. She eventually succumbed to her disease, 5 years after her initial diagnosis. Her functional status remained excellent for four and a half of those years.

Treatment Patterns of Elderly Cancer Patients

There are multiple studies that point to the under-treatment of cancer in the elderly, for both lung cancer and other diseases [93]. Published data from the SEER database showed that the frequency of limited resections increased with age, with a decline of pneumonectomies and lobectomies with age. Approximately, 30% of the most elderly patients in the database were denied surgery or were offered only palliative surgery, in contrast with only 8% of the youngest patients [54]. Age is associated with declines in functional reserve and organ function, and optimal treatment is often affected by co-morbid conditions. Adding to the complexity involved in treatment, the elderly have often not participated in clinical trials, often forcing clinicians to rely primarily on retrospective data for treatment decisions [94].

TABLE 48.2 Life expectancy by age, USA, 2004

Age	Total	Male	Female
65	18.7	17.1	20.0
70	15.1	13.7	16.2
75	11.9	10.7	12.8
80	9.1	8.2	9.8
85	6.8	6.1	7.2
90	5.0	4.4	5.2

Source: Data from [97]

Using 2004 data, the life expectancy of an 80-year-old in the USA is 9.1 years (8.2 years for males, 9.8 years for females), whereas the median survival for elderly patients with untreated early-stage lung cancer is only 14 months [95]. This suggests that life limitation for an 80-year-old with lung cancer is likely to be cancer related [96]. Table 48.2 [97] shows life table data from 2004 for patients older than 65.

Summary Recommendations

Resection of pulmonary malignancies has been shown to be safe in selected elderly patients. Age alone should not be a contraindication to a therapy that offers the best chance for cure for early-stage cancer patients. A thorough preoperative assessment can help individualize the morbidity and mortality risk of surgery for each patient, and thus provide both surgeon and patient with the information needed for operative decision-making. Operative interventions in the elderly require coordinated attention to the specific requirements of the aged. Efforts must be made to balance complete oncologic resection with the elderly's limited tolerance for homeostatic insult. Specialized multidisciplinary care provided by primary-care physicians, geriatric specialists, cardiologists, oncologists, surgeons, anesthesia, nursing, physical therapy, and nutrition optimize care for the elderly thoracic surgery patient.

Section VII
Cardiovascular System

Chapter 49 Invited Commentary

Timothy J. Gardner

Cardiovascular illnesses in the elderly are, in many respects, a natural consequence of aging. The aging process is associated with degeneration of organs and their functions, including the brain, heart, musculoskeletal system, and vascular system. Cardiovascular illnesses, such as ischemic heart disease, peripheral vascular disease, and congestive heart failure can be expected to occur in some form or other as we age; and nearly everyone who survives into their eighties has evidence of cardiovascular pathology. It is interesting that when questioned about their preferred mode of demise, many older people indicate that they would choose to sustain a sudden fatal cardiac event over such unpleasant terminal illnesses as cancer, stroke, dementia, or other afflictions of the elderly.

Many of the dramatic advances in the management of cardiovascular diseases during the past 30 years have been directed toward premature or “unnatural” cardiovascular conditions such as ischemic heart disease in young people, cardiomyopathies causing heart failure in young adults, valvular heart conditions creating disability in middle-aged people, and the like. Coronary bypass grafting and percutaneous coronary angioplasty were offered initially only to young patients with disabling angina. Heart transplantation was undertaken initially only in patients 50 years or younger. Even today, cardiac transplantation is considered inappropriate for people in their late fifties and older.

Along with the survival improvement and increased longevity for young people with heart disease that has occurred over the past two to three decades, the general population, especially in prosperous and developed countries, has been blessed with increasing longevity, as many preventable causes of early deaths are being dealt with successfully. With the enhanced life expectancy, has come changing expectations among our aging fellow citizens. Retirement is no longer viewed as the end of one’s useful lifetime, but rather, as a

period of enrichment during which the rewards of a productive life can be realized and enjoyed. One’s ability to function successfully as an elderly member of society – that is, being able to remain independent and to participate in a variety of important social, physical, and intellectual activities – ends up defining one’s quality of life. If an elderly individual develops a cancer that is unfavorable for successful treatment, that patient and his or her family usually accept the inevitability of death and attempt to deal with the pain and suffering associated with the disease and the need to prepare for dying. The prevailing attitude toward many cardiovascular conditions in the elderly, however, is often different. We often do not accept as readily the inevitability of continued deterioration and death from cardiovascular illnesses, even when such problems occur in older individuals.

What, then, should be the proper approach to cardiovascular disease in the elderly? Because heart and vascular diseases are a natural consequence of aging, should we develop limits indicating at what age one should cease and desist from treating the cardiovascular condition invasively and let “nature takes its course?” Should a patient’s age of 75 or 80 become the cutoff for such advanced cardiovascular therapies as angioplasty, coronary bypass grafting, or placement of internal cardiac defibrillators? On the other hand, in view of our observation that most elderly people want to live as long as possible with a suitable quality of life, should we offer aortic valve replacement to the octogenarian who is functionally intact except for heart-related episodes of syncope from isolated critical aortic valve stenosis? Should we broaden the criteria for eligibility for heart transplantation to old patients who may, in fact, have an extended life expectancy if the current disabling heart failure is adequately managed by cardiac transplantation? There are no easy answers to these and similar questions. They involve a host of considerations beyond the scope of whether an operation can be done safely on a given patient or if there are identifiable preoperative patient characteristics that allow accurate risk factor analysis.

What must be acknowledged by all who are concerned with health care for the elderly is that there will be a continuing and

dramatic increase in the percent of elderly in the population and a notable increase in the number of those surviving beyond 80 years of age. Because of the nature of cardiovascular illnesses, it is likely that such conditions will predominate among our aging population, and that illnesses such as unstable angina in an 80-year-old woman who is living alone successfully will mandate interventional treatment even though the risk of death or complications with angioplasty or surgery is increased. Likewise, the 85-year-old man who is living comfortably in a retirement home, but develops an acute myocardial infarction should be given the opportunity to receive intravenous thrombolytic therapy despite his age and despite the increased risk of adverse bleeding events.

The challenge that must be faced when considering the expanded application of advanced or invasive therapies for cardiovascular disease in the elderly is that of defining and predicting the expected outcomes of various treatments in terms of immediate and long-term survival along with complications, morbidities, and the restoration of one's quality of life. Epidemiologic methods and techniques should be used in an attempt to account for survival differences among elderly patients with specific cardiovascular conditions. Using such information, risk profiles that are based on the individual's health characteristics and are predictive of treatment success or failure can be developed and discussed before undertaking advanced treatments.

In addition, it is mandatory to recognize differences between elderly patients and younger individuals with cardiovascular illnesses. Even such simple concepts as variations in pharmacokinetics in an old patient compared to that in the young, "general population" in whom most clinical trials have been performed becomes an important challenge. For example, despite the fact that there may be statistically validated efficacy associated with the use of a β -blocker for certain cardiovascular conditions, such a medication when used in an elderly patient may result in disabling complications, such as syncope or heart block. Percutaneous coronary angioplasty or intraarterial stenting from the usual femoral

artery approach may be precluded in the elderly patient with severe peripheral vascular disease. Coronary artery bypass grafting, which has negligible mortality risks in otherwise healthy young patients, is much riskier even in the "healthy" elderly patient, with a substantially higher likelihood of death or disabling stroke.

Treatments for cardiovascular illness that, when successful, prolong life and enhance the quality of that life should not be withheld from an elderly patient simply based on that individual's age. On the other hand, we must recognize that invasive therapies, including catheter interventions and especially major surgical procedures, are likely to be less successful and more often associated with complications because of age-related comorbidities and other degenerative conditions. To determine accurately the risk-benefit relation of a suggested treatment, we must be able to stratify the risks according to the patient's individual characteristics including his or her advanced age. Successful treatment of the elderly individual with cardiovascular disease requires also the committed interest and attention of specialists who are willing and able to view their elderly patients with the same discrimination that pediatric specialists are called upon to utilize when caring for young children.

Finally, a commitment to preserve and sustain the useful life of our elderly patients must be supported by a societal commitment to support advanced medical therapies for these individuals. In virtually every developed country of the world, health care for the elderly is provided through government support for medical care. Each society must continuously renew its commitment to supporting and caring in the most appropriate way for its elderly citizens. The challenge and responsibility for those in medicine is to provide advanced medical care to elderly patients only when it is appropriate, that is, when it can be expected to sustain useful life for that patient. The challenges of the aging society, which we will face for the foreseeable future, are immense. It is predictable that much of the focus in medical care will remain on management of cardiovascular illnesses in the elderly.

Chapter 50

Physiologic Changes in Cardiac Function with Aging

Wilbert S. Aronow and William H. Frishman

Age-related changes in the cardiovascular system, overt and occult cardiovascular disease, and decreased physical activity affect cardiovascular function in older persons. With aging, there is a loss of myocytes in both the left and right ventricles with a progressive increase in myocyte cell volume per nucleus in both ventricles [1]. There is also a progressive decrease in the number of pacemaker cells in the sinus node, with only 10% of the number of cells present at age 20 remaining at age 75 [2].

Gonzalez et al. [3] have shown in an animal model that chronologic age also leads to telomeric shortening in cardiac progenitor cells. Aging affects the growth and differential potential of cardiac stem cells, interfering not only with their ability to sustain physiologic cell turnover but also with their capacity to adapt to increases in pressure and volume loads [4, 5].

Afterload

Resistance to the ejection of blood by the left ventricle (LV) is termed afterload. There are two components to afterload: peripheral vascular resistance (PVR) and characteristic aortic impedance. PVR is the steady-state component and provides opposition to steady blood flow. Characteristic aortic impedance is the dynamic component and opposes pulsatile blood flow. PVR is calculated by dividing the mean arterial pressure by the cardiac output; it is inversely proportional to the cross-sectional area of the PV beds. Characteristic aortic impedance is measured as the time variation in mean arterial pressure/flow through the aorta; it is inversely proportional to the arterial compliance (the distensibility of the arterial wall). An indirect measurement of afterload is the pulse wave velocity, which measures the propagation speed of pressure

waves traveling from proximal to distal arterial segments; it increases as arteries become less compliant.

With aging, the large elastic arteries become dilated with a decrease in compliance [6]. Progressive thickening of the aortic media and intima are associated with aortic enlargement [7]. There is an age-associated increase in arterial stiffness resulting from changes in the arterial media, such as thickening of the smooth muscle layers, increased fragmentation of elastin, an increase in the amount and characteristics of collagen, and increased calcification [8]. These structural changes are associated with a decrease in aortic distensibility due to increased aortic stiffness with an increase in pulse wave velocity [9]. The structural changes in the arterial wall are independent of coexisting atherosclerosis. Avolio et al. [9] showed an increase in pulse wave velocity with age in farmers from Guanzhou Province in southern China despite a low prevalence of atherosclerosis in this population. The age-associated increase in stiffness and decrease in distensibility of large elastic arteries is not found in distal arteries [10].

Impedance spectral patterns have demonstrated an age-related increase in characteristic aortic impedance and PVR [11]. The decrease in arterial PV vascular beds [11]. PVR was not age-related in healthy persons screened for occult coronary artery disease (CAD) in the Baltimore Longitudinal Study of Aging [12], but increased with age in persons not screened for occult CAD [13]. Arterial stiffening appearing as an increase in pulse wave velocity is associated with degeneration of the vascular media independent of atherosclerosis. Arterial stiffening causes earlier occurrence of wave reflection from peripheral sites to the ascending aorta during LV ejection. Therefore, aortic and carotid phasic pressures increase to a greater magnitude at a later time during LV ejection, causing an increase in systolic and pulse pressures and a delayed peak in the aortic pressure pulse contour.

Circulating levels of catecholamines increase with age, especially with stress, although β -adrenergic vasodilation of vascular smooth muscle decreases [14]. α -Adrenergic vasoconstriction of vascular smooth muscle does not change with age [15]. The impaired vasodilator response to β -adrenergic

stimulation with age is most important during exercise and contributes to the increased afterload associated with aging.

Increased afterload results in an increase in blood pressure. With aging, there is an increase in systolic blood pressure (SBP) and a widened pulse pressure. A slight reduction in diastolic blood pressure occurs after the sixth decade [16]. The increase in SBP is due to interactions of aging, cardiovascular disease, and lifestyle factors, such as dietary sodium intake, body weight, and level of physical activity. An age-associated increase in the index of aortic stiffening was not found in normotensive persons on a low sodium chloride diet [17]. The increase in carotid augmentation index (an index of aortic stiffening) in highly trained elderly men was half of that expected on the basis of age alone [18]. The prevalence of abnormal aortic stiffness increases steeply in the community with advancing age, especially in the presence of diabetes mellitus and obesity [19].

As aortic compliance decreases with aging, the transfer of kinetic energy from the blood ejected during LV systole to potential energy stored in the elasticity of the aortic wall is reduced. Consequently, return of the potential energy stored in the elasticity of the aortic wall back to the kinetic energy of blood flow during diastole also is reduced. Therefore, the LV must eject its stroke volume into a less compliant aorta with greater pressure and force to achieve adequate cardiac output. The increased pulse wave velocity also causes the pressure in the aorta to increase and peak later during systole, contributing to the increased SBP and widened pulse pressure.

Posterior LV wall thickness increased with increasing age in normotensive men and women screened for occult CAD in the Baltimore Longitudinal Study of Aging [20]. Data from persons in this study suggested that the increase in LV wall thickness associated with aging is mediated by an increase in SBP. Aging is also associated with an increase in the prevalence of hypertension and cardiovascular disease and, therefore, with the LV hypertrophy (LVH) seen by echocardiography.

Age-associated LVH is caused by an increase in the volume but not in the number of cardiac myocytes. Fibroblasts undergo hyperplasia, and collagen is deposited in the myocardial interstitium. Increased afterload results in increased LV systolic stress, and the addition of sarcomeres, in parallel, causes increased LV wall thickness with a normal or reduced LV chamber size and an increased relative wall thickness.

In the Framingham Heart Study, echocardiographic LVH was observed in 33% of men and 49% of women older than 70 years [21]. In our elderly population, echocardiographic LVH was found in 226 of 554 men (41%) with a mean age of 80 years and in 539 of 1,243 women (43%) with a mean age of 82 years [22].

In our elderly population, systolic or diastolic hypertension was present in 255 of 664 men (38%) with a mean age of 80 years and in 651 of 1,488 women (44%) with a mean

age of 82 years [23]. In another study of our elderly population, systolic or diastolic hypertension occurred in 108 of 215 Blacks (50%) with a mean age of 81 years, in 411 of 1,140 Whites (36%) with a mean age of 82 years, and in 19 of 54 Hispanics (35%) with a mean age 81 years [24]. Echocardiographically diagnosed LVH occurred in 66 of 92 hypertensive Blacks (72%), in 194 of 346 hypertensive Whites (56%), and in 8 of 15 hypertensive Hispanics (53%) [24]. However, it was observed in only 2 of our 88 elderly persons (2%) without hypertension or overt cardiac disease [25].

Regular aerobic endurance exercise attenuates age-related decreases in central arterial compliance and restores levels in previously sedentary healthy middle-aged and elderly men [26]. Regular aerobic endurance exercise also can prevent the age-associated loss in endothelium-dependent vasodilation and restore levels in previously sedentary middle-aged and elderly healthy men [27]. These are mechanisms by which regular aerobic endurance exercise contributes to a reduced risk of cardiovascular disease in the elderly [26, 27].

Preload

Preload is the filling volume of the LV. Preload is determined by many factors that influence blood return to the heart and by the mechanical properties of the heart during diastolic filling of the LV.

Resting LV end-diastolic volume, measured by radionuclide ventriculography using multiple gated pool acquisition imaging or by echocardiography, is not age-related in healthy persons, indicating that the resting preload does not change with age [6, 12, 28]. Although resting preload does not change with age, LV early diastolic filling decreases with age.

Passive filling of the LV occurs during the rapid filling and diastasis phases of early diastole. With age, LV stiffness is increased, LV compliance reduced, LV wall thickness increased, LV relaxation impaired, and LV early diastolic filling reduced. This may result in hypotension if preload is reduced. An age-related increase in SBP also decreases LV early diastolic filling, leading to hypotension if preload is decreased. LV filling during early diastole is reduced 50% from age 20 to 80 [6, 29, 30].

Despite the decrease in early diastolic filling of the LV with age, preload is maintained because left atrial contraction becomes more vigorous to increase late diastolic filling of the LV [6, 28–34]. Augmentation of late diastolic filling of the LV prevents a reduction in LV end-diastolic volume. The ratio of late diastolic Doppler peak transmitral velocity (peak atrial, or A wave, velocity) to early diastolic Doppler peak transmitral velocity (peak rapid filling, or E wave, velocity) increases from approximately 0.6 at 30 years of age to 1.2 at 70 years of age [35]. A reduction in the E/A wave ratio with

age reflects a decrease in LV compliance. An age-related increase in left atrial size resulting from increased wall stress due to increased left atrial pressure counteracts the effects of reduced LV compliance with age. In our older population, 619 of 1,797 older persons (34%) had echocardiographic left atrial enlargement [22].

Age was the most powerful independent variable LV filling in healthy persons in the Framingham Heart Study [36]. Age was inversely associated with the E wave (peak early diastolic filling velocity) and was directly associated with the A wave (peak late diastolic filling velocity). Other independent variables that contributed to a lesser degree to LV filling were heart rate, PR interval measured from the electrocardiogram (ECG), gender, LV systolic function, and SBP. Increasing the heart rate decreases peak early diastolic filling and increases peak late diastolic filling velocity. The PR interval on the ECG is inversely associated with peak early diastolic filling velocity. Women have slightly higher peak early diastolic filling velocities than men. LV systolic function is directly associated with peak early diastolic filling velocity. Increasing the SBP increases the peak late diastolic filling velocity [36, 37]. Age-associated abnormalities in Doppler measures of myocardial filling and relaxation are only partially minimized by lifelong endurance training [38].

A decrease in preload is not well tolerated in older persons. Decreased intravascular volume, reduced venous return to the heart, vasodilation by drugs or disease states, and use of drugs such as nitrates or diuretics decrease preload and may cause reduced cardiac output and hypotension in older persons. Reduced compliance of the LV and decreased cardiac and vascular responsiveness to β -adrenergic stimulation [39] cause elderly persons to be highly dependent on the Frank–Starling mechanism to increase cardiac output. Older persons are more susceptible to developing orthostatic hypotension [40–42]. Impaired baroreceptor reflex sensitivity [43], reduced cardiac responsiveness to β -adrenergic stimulation [36], loss of arterial compliance, reduced venous return due to increased venous distensibility, impaired compensatory mechanisms for maintenance of fluid volume and electrolyte balance, increased incidence of common precipitating diseases and disorders, and the use of multiple drugs contribute to orthostatic hypotension. Older persons are also more susceptible to developing postprandial hypotension [43–46].

Marked decreases in postprandial SBP in the elderly may predispose them to symptomatic hypotension and to falls, syncope, angina pectoris, and transient cerebral ischemic attacks [44–48]. At 29-month follow-up, a marked reduction in postprandial SBP in older persons was associated with an increased incidence of falls, syncope, new coronary events, new stroke, and total mortality [48]. Whether therapeutic interventions to prevent a marked decrease in postprandial SBP in elderly persons can reduce the incidence of these outcomes at long-term follow-up must be investigated.

Because left atrial contraction can contribute up to 50% of LV filling in a poorly compliant LV, the development of atrial fibrillation may result in a marked decrease in cardiac output because of loss of the left atrial contribution to LV late diastolic filling. A rapid ventricular rate associated with atrial fibrillation also decreases the time for diastolic filling of the LV, resulting in a marked reduction in cardiac output.

The incidence of chronic atrial fibrillation also is increased with age [49, 50]. In 2,101 elderly persons in a nursing home, the prevalence of chronic atrial fibrillation was 5% in persons aged 60–70 years, 13–14% in persons aged 71–90 years, and 22% in persons aged 91 years and older [50]. Atrial fibrillation in old persons is associated with an increased incidence of new thromboembolic stroke [49, 50] and new coronary events [51, 52].

Cardiac output increases during exercise in healthy old persons owing to an increase in venous return to the heart, increasing the diastolic filling of the LV and allowing an increased stroke volume to be ejected during exercise (Frank–Starling mechanism) [53]. The maximal heart rate response to exercise decreased with age in healthy subjects in the Baltimore Longitudinal Study of Aging [12], whereas exercise stroke volume increased with age to maintain the exercise cardiac output. The increase in exercise stroke volume resulted from an increase in LV end-diastolic volume (preload) via the Frank–Starling mechanism. In contrast, healthy nonelderly persons achieved an increase in exercise cardiac output primarily by an increase in heart rate. Exercise stroke volume increased in nonelderly healthy persons owing to a slight increase in the LV end-diastolic volume and a large reduction in the LV end-systolic volume. The exercise-induced increase in heart rate and decrease in LV end-systolic volume in nonelderly persons is probably mediated by β -adrenergic stimulation. The increase in LV end-diastolic volume during exercise in healthy older persons suggests that the age-associated decrease in resting early diastolic filling of the LV does not persist during exercise.

Contractility

The intrinsic ability of the heart to generate force does not change with age in healthy persons, although the duration of contraction and relaxation is prolonged in senescent animals [54, 55]. Prolongation of the LV ejection time [56] and the pre-ejection period [57] with age in healthy persons indicates that prolongation of contraction occurs with age. Prolongation of the duration of contraction in senescent animals is associated with increased muscle stiffness and prolongation of the action potential duration [58]. These age-related changes are associated with cellular changes in the excitation-contraction coupling mechanism [59] and are an adaptive response to

preserve contractile function in response to an age-induced increase in afterload.

There is no decrease in resting LV ejection fraction (LVEF) or circumferential fiber shortening in old persons with no evidence of heart disease [6, 12, 28, 60, 61]. However, systolic function with exercise decreases with age. In the Baltimore Longitudinal Study of Aging, old persons showed less exercise-induced increase in LVEF than did younger persons because of an age-related increase in LV end-systolic volume [12]. However, the absolute values of LVEF at maximal exercise LV ventricular contractility in healthy old persons during maximal exercise are manifestations of reduced β -adrenergic responsiveness, with aging partially offset by exercise-induced dilation of the LV [62].

Diastolic Function

Aging is associated with prolongation of the isovolumic relaxation time, decreased early diastolic filling of the LV, and augmented late diastolic filling of the LV [29, 32, 35]. Normal aging changes that affect the LV diastolic function include increased SBP, increased LV wall thickness, reduced LV early diastolic filling, prolonged LV diastolic relaxation, increased left atrial size, and increased LV late diastolic filling [63].

With age occurs slowing of the rate at which calcium is sequestered by the sarcoplasmic reticulum following myocardial excitation, which causes decreased relaxation of the LV [59, 64, 65]. Accumulation of calcium at the onset of diastole may decrease LV diastolic relaxation and early diastolic filling [64]. Decreased oxidative phosphorylation and cumulative mitochondrial peroxidation occurring with age may also decrease the LV diastolic function [66, 67].

Increased LV stiffness with age due to increased interstitial fibrosis and cross-linking of collagen in the heart impairs LV diastolic relaxation and filling [1, 68–70]. Myocardial ischemia in the absence of CAD caused by decreases in capillary density and coronary reserve with age may further reduce LV diastolic function in old persons [1, 71].

In addition to a decrease in LV diastolic relaxation and early diastolic filling caused by age, old persons are more likely to have LV diastolic dysfunction because they have an increased prevalence of hypertension, myocardial ischemia due to CAD, and LVH due to hypertension, CAD, valvular aortic stenosis, hypertrophic cardiomyopathy, and other cardiac disorders. The increased stiffness of the LV and prolonged LV relaxation time reduce LV early diastolic filling and cause higher LV end-diastolic pressures at rest and during exercise in old persons [72, 73].

In patients with congestive heart failure (CHF) associated with LV systolic dysfunction, the LVEF <50%. Amount of

myocardial fiber shortening is reduced, the stroke volume is decreased, the LV is dilated, and the patient is symptomatic.

With CHF, due to LV diastolic dysfunction with normal LV systolic function, the LVEF is normal. Kitzman et al. [74] showed that during exercise, persons with CHF and normal LV systolic function but abnormal LV diastolic function were unable to increase stroke volume normally, even in the presence of increased LV filling pressure. Myocardial hypertrophy, ischemia, or fibrosis causes slow or incomplete LV filling at normal left atrial pressures. The left atrial pressure increases to augment left ventricular filling, resulting in pulmonary and systemic venous congestion. The development of atrial fibrillation may also cause a decrease in cardiac output and the development of pulmonary and systemic venous congestion because of loss of the left atrial contribution to LV late diastolic filling and reduced diastolic filling time due to a rapid ventricular rate.

In a prospective study of 2,535 persons older than 60 years (mean 82 years), CHF developed in 677 persons (27%) [75]. In a prospective study of 1,160 men and 2,464 women older than 60 years, mean age 81 years, CHF developed in 29% of older men and in 26% of older women [76]. Elderly persons are more likely than nonelderly persons to develop CHF because of abnormal LV diastolic dysfunction with normal LV systolic function. Table 50.1 shows that the prevalence of normal LVEF in older persons with CHF ranges from 34 to 52% [75, 77–82]. The prevalence of normal LVEF with CHF is also higher in old women than in old men [75, 78–82].

A normal LVEF was present in older persons with CHF in 44% of 55 African-American men versus 58% of 110 African-American women, in 46% of 24 Hispanic men versus 56% of 34 Hispanic women, in 35% of 148 white men versus 57% of 303 white women, and in 38% of 227 older men versus 57% of 447 older women [82]. Table 50.2 shows the prevalence of a normal LVEF in 572 older persons with CHF in men and women of different age groups [75]. In the

TABLE 50.1 Prevalence of normal left ventricular ejection fraction (LVEF) in older persons with congestive heart failure (CHF)

Study	Results for patients with CHF and normal LVEF
Wong [77]	41% of 54 persons, mean age 80 years
Aronow [78]	47% of 247 persons, mean age 82 years
Cardiovascular Health Study [79]	59% of 186 persons, mean age 73 years
Framingham Heart Study [80]	51% of 73 persons, mean age 73 years
Pernenkil [81]	34% of 501 persons, mean age 81 years
Aronow [75]	50% of 572 persons, mean age 82 years
Aronow [82]	51% of 674 persons, mean age 81 years

TABLE 50.2 Association of congestive heart failure with normal left ventricular ejection fraction with gender and age in 572 older persons

Age (years)	Normal left ventricular ejection fraction
60–69	22% of 18 men and 37% of 38 women
70–79	33% of 54 men and 44% of 79 women
80–89	41% of 86 men and 59% of 219 women
≥90	47% of 19 men and 73% of 59 women
All ages	37% of 177 men and 56% of 395 women with congestive heart failure

Source: Adapted from Aronow et al. [75]

community, advancing age and female gender are associated with increases in vascular and ventricular systolic and diastolic stiffness even in the absence of cardiovascular disease [83]. This contributes to the increased prevalence of CHF with a normal LVEF in elderly persons, especially in elderly women.

LVEF should be measured in all patients with CHF in order that appropriate therapy may be given [84–88]. For example, digoxin should not be used to treat persons with CHF and normal LVEF if sinus rhythm is present [63, 89–93]. By increasing contractility through increasing intracellular calcium ion concentration, digoxin may increase LV stiffness, increasing left ventricular filling pressure, and adversely affecting CHF due to LV diastolic dysfunction. Patients with CHF due to abnormal LVEF tolerate higher doses of diuretics than do patients with CHF and normal LVEF. Patients with CHF due to LV diastolic dysfunction with normal LVEF need high LV filling pressures to maintain an adequate stroke volume and cardiac output and cannot tolerate intravascular depletion. These patients should be treated with a low-salt diet with cautious use of diuretics, rather than with large doses of diuretics. Patients with abnormal LVEF should not be treated with calcium channel blockers [94, 95].

Cardiovascular Response to Exercise

The maximal oxygen consumption (VO_{2max}) is the best overall measurement of cardiovascular fitness [96]. VO_{2max} is the product of cardiac output and systemic arteriovenous oxygen difference at peak exercise. Maximal cardiac output – the heart rate multiplied by the stroke volume at peak exercise – is a more direct measurement of cardiovascular reserve than is VO_{2max} [96]. VO_{2max} is reduced with age [97, 98]. The degree of reduction of VO_{2max} with age is affected by physical conditioning, subclinical CAD, smoking, and body weight. Table 50.3 lists the cardiovascular responses to exercise in healthy old persons.

In the Baltimore Longitudinal Study of Aging, older male athletes had a higher peak exercise VO_{2max} than older sedentary men [99]. The greater peak exercise VO_{2max} in older male athletes than in older sedentary men was achieved by a higher

cardiac index and a greater systemic arteriovenous oxygen difference. The higher peak exercise cardiac index in older male athletes than in older sedentary men was due to a higher stroke volume index with similar maximal heart rates. Long-term endurance training also is associated with enhanced ventricular diastolic filling indices [100]. Older age is associated with a reduced exercise efficiency and an increase in the oxygen cost of exercise, which contributes to a reduced exercise capacity. These age-related changes are reversed with exercise training [101].

A reduction in maximal systemic arteriovenous oxygen difference occurs with age [102]. The decrease in muscle mass with age may play a major role in the decrease in systemic arteriovenous oxygen difference at peak exercise and in VO_{2max} [103].

Fleg et al. [104] also investigated the effect of age on peak upright cycle exercise in healthy sedentary men and women aged 22–86 years in the Baltimore Longitudinal Study of Aging. Peak cycle work rate was reduced with age in both men and women but was greater in men than in women at any age. Both men and women had peak exercise reductions in heart rate, cardiac index, and LVEF and increases in the LV end-diastolic volume index and end-systolic volume index with age. Peak exercise stroke volume index did not vary with age in men or women. The exercise-induced decrease in LV end-systolic volume index and the increases in cardiac index, stroke volume index, and LVEF from rest were greater in older men than in older women.

Age-Related Changes in Cardiovascular Function

Table 50.3 lists some age-related changes in cardiovascular function in healthy old persons. Contractility at rest does not change with age, but the duration of LV contraction and relaxation is prolonged. Age-associated reductions in maximal heart rate and in LV contractility during maximal exercise are manifestations of reduced β -adrenergic responsiveness with age partially offset by exercise-induced dilation of the LV.

Reduced arterial compliance contributes more to the age-related increase in afterload than does the loss of peripheral vascular beds. The impaired vasodilator response to β -adrenergic stimulation with age is most important during exercise and contributes to the increased afterload associated with age. Resting preload does not change with age. LV early diastolic filling is reduced with age. Augmentation of late diastolic filling of the LV prevents a reduction in LV end-diastolic volume with age. The maximal heart rate response to exercise is reduced with age. Exercise stroke volume is increased with age to maintain

TABLE 50.3 Cardiovascular responses to exercise in healthy old persons

Maximal heart rate is reduced with age
Exercise stroke volume is increased with age to maintain cardiac output
Increased exercise stroke volume with age results primarily from increase in LV end-diastolic volume by Frank–Starling mechanism
Reduction in muscle mass with age plays role in age-associated decreases in systemic arteriovenous oxygen difference and in VO_{2max} at peak exercise
LV end-diastolic and end-systolic volumes are increased during peak exercise with age
Peak exercise LV ejection fraction is reduced with age
Exercise-induced decrease in the LV end-systolic volume index and increases in the cardiac index, stroke volume index, and LV ejection fraction from rest are greater in old men than in old women
Contractility at rest does not change with age
Duration of LV contraction and relaxation is prolonged with age
Reduction in arterial compliance contributes more to age-related increase in afterload than does loss of peripheral vascular beds
Resting preload does not change with age
LV early diastolic filling is reduced with age
Augmentation of late diastolic filling of the LV prevents a reduction in LV end-diastolic volume with age
Age-associated reductions in maximal heart rate and LV contractility during maximal exercise are manifestations of reduced β -adrenergic responsiveness with age partially offset by exercise-induced dilation of the LV
<u>Aging selectively impairs endothelium-dependent function</u>

LV left ventricle, left ventricular

the exercise cardiac output, resulting from an increase in preload by the Frank–Starling mechanism. VO_{2max} and the systemic arteriovenous oxygen difference at peak exercise are reduced with age. Aging also selectively impairs endothelium-dependent function [105].

In addition to age-related changes in cardiovascular function and deconditioning due to a sedentary lifestyle, old persons also have a higher prevalence and incidence of cardiovascular disorders that impair cardiovascular performance than do nonelderly persons. Old persons are more likely than nonelderly persons to develop CHF secondary to abnormal LV diastolic dysfunction with normal LV systolic function.

Treatment of Congestive Heart Failure

The LVEF should be measured in all persons with CHF so appropriate therapy may be given [84–88]. For example, digoxin should not be used to treat persons with CHF and

normal LVEF if a sinus rhythm is present [63, 89–93]. Large doses of diuretics and nitrates should also be used cautiously in persons with CHF and a normal LVEF [95].

Calcium channel blockers such as diltiazem, nifedipine, and verapamil exacerbate CHF associated with abnormal LVEF [106]. Diltiazem increased mortality in patients with pulmonary congestion associated with abnormal LVEF after myocardial infarction [107]. The Multicenter Diltiazem Postinfarction Trial showed, in persons with a LVEF less than 40%, that late CHF at follow-up was increased in patients randomized to diltiazem (21%) versus those randomized to placebo (12%) [108]. Prospective studies have found that the vasoselective calcium channel blockers amlodipine [109] and felodipine [110] did not significantly affect survival compared with placebo in patients with CHF associated with abnormal LVEF. There was a significantly higher incidence of pulmonary edema in the persons treated with amlodipine (15%) than in persons treated with placebo (10%) [109]. The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines recommend that calcium channel blockers should not be given to persons with CHF associated with abnormal LVEF [94].

Abnormal Left Ventricular Ejection Fraction

Table 50.4 shows the ACC/AHA Class I recommendations for treating patients with current or prior symptoms of CHF with reduced LVEF [94]. Older persons with CHF associated with abnormal LVEF should be treated with a low sodium diet and with diuretics plus an angiotensin-converting enzyme (ACE) inhibitor [111, 112] plus a β -blocker such as metoprolol CR/XL [113], carvedilol [114], bisoprolol [115], or nebivolol [116]. An angiotensin receptor blocker should be used if the patient is intolerant to an ACE inhibitor because of cough or angioneurotic edema [117]. Regular physical activity such as walking should be encouraged in patients with mild to moderate HF to improve functional status and to decrease symptoms. Patients with CHF who are dyspneic at rest at a low work level may benefit from a formal cardiac rehabilitation program [118].

An implant cardioverter defibrillator and cardiac resynchronization therapy should be used according to ACC/AHA guidelines [94, 119–121]. An aldosterone antagonist such as spironolactone [122] or eplerenone [123] should be used according to ACC/AHA guidelines [94].

Table 50.5 shows the ACC/AHA Class IIa recommendations for treating patients with current or prior symptoms of CHF with reduced LVEF [94]. Isosorbide dinitrate plus hydralazine was very effective in treating Blacks with CHF

TABLE 50.4 Class I recommendations for treating persons with current or prior symptoms of heart failure with decreased left ventricular ejection fraction

Treat underlying and precipitating causes of heart failure
Use diuretics and salt restriction in persons with fluid retention
Use ACE inhibitors
Use β -blockers
Use angiotensin II receptor blockers if intolerant to ACE inhibitors because of cough or angioneurotic edema
Avoid or withdraw nonsteroidal anti-inflammatory drugs, most antiarrhythmic drugs, and calcium channel blockers
Recommend exercise training
Implant cardioverter-defibrillator in persons with a history of cardiac arrest, ventricular fibrillation, or hemodynamically unstable ventricular tachycardia
Implant cardioverter-defibrillator in persons with ischemic heart disease ≥ 40 days postmyocardial infarction or nonischemic cardiomyopathy, a LVEF $\leq 30\%$, NYHA Class II or III symptoms on optimal medical therapy, and an expectation of survival of ≥ 1 year
Use cardiac resynchronization therapy in persons with a LVEF $\leq 35\%$, NYHA Class III or IV symptoms despite optimal therapy, and a QRS duration >120 ms
Add an aldosterone antagonist in selected patients with moderately severe to severe symptoms of heart failure who can be carefully monitored for renal function and potassium concentration (serum creatinine should be ≤ 2.5 mg/dl in men and ≤ 2.0 mg/dl in women; serum potassium should be <5.0 mEq/l)

Source: Adapted from Hunt et al. [94]

ACE angiotensin converting enzyme, LVEF left ventricular ejection fraction, NYHA New York Heart Association

TABLE 50.5 Class IIa recommendations for treating persons with current or prior symptoms of heart failure with decreased left ventricular ejection fraction

Angiotensin II receptor blockers may be used instead of ACE inhibitors if patients are already taking them for other reasons
Add hydralazine plus a nitrate to patients with persistent symptoms
Implant cardioverter-defibrillator in patients with LVEF of 30–35% from any origin with NYHA Class II or III symptoms on optimal medical therapy with a life expectancy of >1 year
Digoxin can be used in patients with persistent symptoms to reduce hospitalization for heart failure

Source: Adapted from Hunt et al. [94]

ACE angiotensin converting enzyme, LVEF left ventricular ejection fraction, NYHA New York Heart Association

in the African-American Heart failure trial [124, 125]. The serum digoxin level should be maintained between 0.5 and 0.8 ng/ml to avoid an increase in mortality [95, 126, 127].

In experimental studies, the recognition of factors enhancing the activation of the cardiac stem cell pool, their mobilization and translocation, however, suggest that the detrimental effects of aging on the heart might be prevented in the future by local stimulation of cardiac stem cells or the intramyocardial delivery of cardiac stem cells following their expansion

TABLE 50.6 Therapy of patients with heart failure and normal left ventricular ejection fraction

Treat underlying and precipitating causes of heart failure
Avoid use of inappropriate drugs such as nonsteroidal anti-inflammatory drugs
Treat hypertension, especially systolic hypertension, hyperlipidemia, myocardial ischemia, and anemia
Treat with cautious use of diuretics
Treat with β -blockers
Treat with angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker if patient cannot tolerate ACE inhibitor because of cough, angioneurotic edema, rash, or altered taste sensation
Add isosorbide dinitrate plus hydralazine if heart failure persists
Avoid digoxin if sinus rhythm is present
Exercise training as an adjunctive approach to improve clinical status in ambulatory patients

Source: Data from Hunt et al. [94]

and rejuvenation in vitro [3, 5, 128]. Cardiac stem cell therapy may become perhaps a novel strategy for the devastating problem of heart failure in the old population.

Normal Left Ventricular Ejection Fraction

Table 50.6 shows the therapy for older persons with CHF associated with a normal LVEF. β -Blockers [116, 129], ACE inhibitors [130, 131], and angiotensin receptor blockers [132] are efficacious in the treatment of these patients.

In older persons with CHF associated with a normal LVEF, pulmonary congestion is reduced by a low sodium diet, diuretics, and nitrates. Sinus rhythm is maintained to increase the LV filling time. The ventricular rate is slowed below 90 beats per minute by a β -blocker to increase LV filling time. Myocardial ischemia should be decreased and is best achieved by giving a β -blocker. Elevated SBP is decreased by diuretics and an ACE inhibitor. The LV mass is reduced by an ACE inhibitor. LV relaxation should be improved by ACE inhibitors or β -blockers.

Cardiovascular Disease

In addition to age-related changes in cardiovascular function and deconditioning due to a sedentary lifestyle, old persons also have a higher prevalence and incidence of cardiovascular disorders, which impair cardiovascular performance, than nonelderly persons. Table 50.7 lists the prevalence of some cardiovascular disorders in an elderly population in a long-term health care facility [76, 133, 134].

TABLE 50.7 Prevalence of cardiovascular disorders in older persons in a long-term health-care facility

Cardiovascular disorder	Mean age (years)	Prevalence	
		Number	%
Coronary artery disease [76]	81	1,521/3,624	42
Thromboembolic stroke [76]	81	1,131/3,624	31
Peripheral arterial disease [76]	81	1,011/3,624	28
40–100% Extracranial carotid arterial disease [133]	81	281/1,846	19
Congestive heart failure [76]	81	978/3,624	27
Hypertension [76]	81	2,136/3,624	59

Left atrial enlargement [134]	81	987/2,805	35

Aortic Valve Disease

Valvular aortic stenosis in old persons is usually due to stiffening, scarring, and calcification of aortic valve leaflets. Calcific deposits in the aortic valve are common and may lead to valvular aortic stenosis [22, 135–137]. Calcific deposits in the aortic valve were present in 22 of 40 necropsied patients (55%) aged 90–103 years [136]. Aortic cuspal calcium was present in 295 of 752 men (36%), mean age 80 years, and in 672 of 1,663 women (40%), mean age 82 years [137].

Calcific valvular aortic stenosis was present at autopsy in 18% of 366 octogenarians [138]. Valvular aortic stenosis was diagnosed by continuous-wave Doppler echocardiography in 463 of 2,805 old persons (17%) with a mean age 81 years [76]. Severe aortic stenosis was present in 2% of these 2,805 old persons [76]. Severe aortic stenosis was also diagnosed in 3% of 501 persons aged 75–86 years in the Helsinki Ageing Study [139].

Aortic valve calcium, mitral annular calcium, and coronary artery disease in older persons have similar predisposing factors for atherosclerosis [137, 139–145]. Older patients with extracranial carotid arterial disease [140] and with peripheral arterial disease [141] have an increased prevalence of aortic stenosis. Older patients with aortic stenosis [146–148] and with valvular aortic sclerosis [148, 149] have an increased incidence of new coronary events.

The prevalence of aortic regurgitation also increases with age [22, 150, 151]. Aortic regurgitation was diagnosed by pulsed Doppler recordings of the aortic valve in 526 of 1,797 old persons (29%) with a mean age of 81 years [76]. Severe or moderate aortic regurgitation was diagnosed by pulsed Doppler recordings of the aortic valve in 74 of 450 old patients with a mean age of 82 years [152]. Margonato et al.

[150] linked the increased prevalence of aortic regurgitation with age to aortic valve thickening.

Mitral Valvular Disease

Two degenerative aging processes – mitral annular calcification and mucoid (or myxomatous) degeneration of the mitral valve leaflets and chordae tendineae – can cause significant mitral valvular dysfunction [153–155]. Mitral annular calcification was diagnosed by two-dimensional echocardiography in 36% of 924 elderly men and in 52% of 1,881 elderly women, mean age 81 years [76]. Mitral annular calcium was present in 11 of 57 persons (19%) 62–70 years of age, in 53 of 158 persons (34%) 71–80 years of age, in 190 of 301 persons (63%) 81–90 years of age, in 75 of 85 persons (88%) 91–100 years of age, and in 3 of 3 persons (100%) 101–103 years of age [156].

Breakdown of lipid deposits on the ventricular surface of the posterior mitral leaflet at or below the mitral annulus and on the aortic surfaces of the aortic valve cusps is probably responsible for the calcification [157]. Elderly men and women with mitral annular calcium have a higher prevalence of CAD [158–160], of peripheral arterial disease [160, 161], of extracranial carotid arterial disease [160, 162, 163], and of aortic atherosclerotic disease [160] than elderly men and women without mitral annular calcium.

Conduction Defects

The increased prevalence of conduction defects in old persons is due to age-related degeneration of the conduction system and to the development of cardiovascular disease.

TABLE 50.8 Prevalence of conduction defects in 1,153 old persons

Defect	Prevalence (%)
First-degree atrioventricular block	6
Left anterior fascicular block	8
Right bundle branch block	10
Left bundle branch block	4
Intraventricular conduction defect	3
Second-degree atrioventricular block	1
Pacemaker rhythm	4

Source: Adapted from Aronow [165]

Aging is associated with regional conduction slowing, anatomically determined conduction delay at the crista, and structural changes including areas of low voltage [164]. Impairment of sinus node function and an increase in atrial refractoriness occur with aging, predisposing to atrial fibrillation [164]. Table 50.8 lists the prevalence of conduction defects in 1,153 old persons, mean age 82 years [165]. At a 45-month follow-up, old persons with second-degree atrioventricular block, left bundle branch block, intraventricular conduction defect, and pacer rhythm had an increased incidence of new coronary events [165]. At the 45-month follow-up, old persons with first-degree atrioventricular block, left anterior fascicular block, or right bundle branch block did not have an increased incidence of new coronary events [165].

Conclusions

Cardiovascular function in elderly persons is significantly affected by the aging process itself and by those acquired diseases of the cardiovascular system that are more prevalent with age. These physiologic and pathologic changes of the aging cardiovascular system must be taken into consideration during the clinical assessment and management of elderly patients who need to undergo surgical procedures and general anesthesia.

Chapter 51

Risk Factors for Atherosclerosis in the Elderly

Wilbert S. Aronow and William H. Frishman

Coronary artery disease (CAD), peripheral arterial disease (PAD), atherothrombotic brain infarction (ABI), and extracranial carotid arterial disease (ECAD) are more common in old individuals than in middle-aged ones. CAD is the leading cause of death in old persons, especially those with PAD, ABI, or ECAD. This chapter discusses risk factors for CAD, PAD, ABI, and ECAD in old persons.

Cigarette Smoking

Coronary Artery Disease

The Chicago Stroke Study demonstrated that current cigarette smokers, age 65–74, had a 52% higher mortality from CAD than nonsmokers, ex-smokers, and pipe and cigar smokers [1]. Ex-smokers who had stopped smoking for 1–5 years had similar mortality from CAD as nonsmokers. The Systolic Hypertension in the Elderly Program pilot project found that smoking was a predictor of a first cardiovascular event and myocardial infarction (MI)/sudden death [2]. During a 30-year follow-up of subjects 65 years of age and older in the Framingham Heart Study, cigarette smoking was not associated with the incidence of CAD but was associated with mortality from CAD [3].

During a 12-year follow-up of men aged 65–74 in the Honolulu Heart Program, cigarette smoking was an independent risk factor for nonfatal MI and fatal CAD [4]. The absolute excess risk associated with cigarette smoking was 1.9 times higher in old men than in middle-aged men. At 5-year follow-up of old subjects (age ≥ 65) in three communities, cigarette smokers were shown to have a higher incidence of cardiovascular mortality than nonsmokers [5]. The relative risk for cardiovascular mortality was 2.0 in male smokers

and 1.6 in female smokers. The incidence of cardiovascular death in former smokers was similar to those who had never smoked [5].

At 40-month follow-up of 664 old men (mean age 80 years) and 48-month follow-up of 1,488 old women (mean age 82 years), cigarette smoking was demonstrated by multivariate analysis to increase the relative risk of new coronary events 2.2 and 2.0 times, respectively (Table 51.1) [6]. During a 42-month mean follow-up of 410 old Blacks and Whites with hypertension (mean age 81), the odds ratio for developing new coronary events was 2.0 in cigarette smokers [7]. It has also been observed that cigarette smoking aggravates angina pectoris and precipitates silent myocardial ischemia in old persons with CAD.

In the Coronary Artery Surgery Study (CASS) Registry, subjects over the age of 65 who continued smoking had an increased risk of developing MI or sudden death compared with those who stopped smoking during the year before enrolling in the study [8]. Furthermore, increasing age did not decrease the beneficial effects of smoking cessation.

In the Bronx Longitudinal Aging Study (BAS), whose cohort consisted of subjects 75–85 years of age at study onset, 10% of the cohort were smoking at study onset, and 46% reported having smoked in the past [8]. In the various BAS multivariate analyses, cigarette smoking history was shown to be an independent predictor of both cardiovascular morbidity and mortality and the development of MI.

Peripheral Arterial Disease

Numerous studies have shown that cigarette smoking is a risk factor for PAD in men and women [9–17]. In a study of 1,911 old subjects (mean age 81 years), current cigarette smoking was shown to increase the prevalence of symptomatic PAD 2.6 and 4.6 times in old men and women, respectively (Table 51.1) [9]. At 43-month follow-up of 291 old subjects (mean age 82 years) with PAD, multivariate analysis demonstrated that cigarette smoking was an independent predictor of new coronary events, with a relative risk of 1.6 [18].

TABLE 51.1 Association of cigarette smoking with new coronary events, peripheral arterial disease, new atherothrombotic brain infarction, and extracranial carotid arterial disease in elderly men and women

Study	Elderly men			Elderly women		
	No. of patients	Mean follow-up (months)	Relative risk	No. of patients	Mean follow-up (months)	Relative risk
Incidence of new coronary events [6]	664	40	2.2	1,488	48	2.0
Prevalence of PAD [9]	467	–	2.6	1,444	–	4.6
Incidence of new ABI [23]	664	42	1.5	1,488	48	1.9
Prevalence of 40–100% ECAD in 1,063 men and women [24]			4.0			

PAD peripheral arterial disease, ABI atherothrombotic brain infarction, ECAD extracranial carotid arterial disease

Atherothrombotic Brain Infarction

A meta-analysis of 32 studies showed that cigarette smoking is a risk factor for ABI in men and women and carries a relative risk of 1.9 [19]. In the Medical Research Council (MRC) Trial, the incidence of strokes was 2.3 times higher in smokers than in nonsmokers [20]. Moreover, nonsmokers who received propranolol as antihypertensive therapy had a reduction in the incidence of stroke that cigarette smokers did not have. In the Framingham Heart Study, during a 26-year follow-up, cigarette smoking increased the incidence of new ABI 1.6 and 1.9 times in men and women, respectively [21]. Furthermore, the incidence of stroke in smokers who used >40 cigarettes daily was twice as high as in those who used <10 cigarettes daily. The impact of cigarette smoking did not diminish with increasing age. The risk of stroke was substantially decreased within 2 years of quitting smoking, with the incidence of stroke returning to the level of nonsmokers 5 years after smoking cessation. Although elderly individuals who quit smoking have higher cerebral perfusion levels than old persons who continue to smoke, their cerebral perfusion levels are lower than those who have never smoked [22].

At 42-month follow-up of 664 old men (mean age 80) and 48-month follow-up of 1,488 old women (mean age 82), cigarette smoking was demonstrated by multivariate analysis to increase the relative risk for ABI 1.5 and 1.9 times in men and women, respectively (Table 51.1) [23].

Extracranial Carotid Arterial Disease

Numerous studies have demonstrated that cigarette smoking is a strong risk factor for ECAD [24–29]. In a study of 1,063 old subjects (mean age 81 years), cigarette smoking was found by multivariate analysis to increase the prevalence of 40–100% ECAD 4.2 times (Table 51.1) [24].

On the basis of the available data, old men and women who smoke should be strongly encouraged to stop. In these individuals, cigarette smoking is a risk factor for CAD, PAD, ABI,

and ECAD, as well as for other disorders including pulmonary disease and lung cancer. Smoking cessation should reduce mortality due to CAD, stroke, and other cardiovascular diseases and all-cause mortality in elderly persons.

Approaches to smoking cessation include the use of nicotine patches or nicotine polacrilex gum, which are available over the counter [30]. If this therapy is unsuccessful, nicotine nasal spray or treatment with the antidepressant bupropion and/or varenicline should be considered [30–32]. A nicotine inhaler may also be used [32]. The dosage and duration of treatment of each of these pharmacotherapies are discussed in detail elsewhere [32]. Concomitant behavioral therapy may also be needed [33]. Repeated physician advice is very important in the treatment of smoking addiction.

Hypertension

Coronary Artery Disease

Increased peripheral vascular resistance is the cause of systolic and diastolic hypertension in old persons. *Systolic hypertension* is diagnosed if the systolic blood pressure is 140 mmHg or higher on three occasions, and *diastolic hypertension* is diagnosed if the diastolic blood pressure is 90 mmHg or higher on three occasions [34]. *Isolated systolic hypertension* is diagnosed when the systolic blood pressure is 140 mmHg or higher on three occasions but diastolic blood pressure is normal [34].

In 1,414 old subjects (mean age 82 years), the prevalence of systolic or diastolic hypertension was higher in Blacks than in Hispanics or Whites [35]. In a study of 1,051 old individuals with hypertension, isolated systolic hypertension occurred in two-thirds of the persons [36]. Although both diastolic and isolated systolic hypertension are associated with increased cardiovascular morbidity and mortality in old individuals, increased systolic blood pressure is the greater risk factor [37].

The higher the systolic or diastolic blood pressure, the greater the morbidity/mortality from CAD in old men and

women. During a 30-year follow-up of subjects 65 years and older in the Framingham Heart Study, systolic hypertension correlated with the incidence of CAD in men and women [3]. Diastolic hypertension correlated with CAD in old men but not in old women. At 40-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, systolic or diastolic hypertension was demonstrated by multivariate analysis to increase the relative risk of new coronary events 2.0 and 1.6 times, respectively (Table 51.2) [6].

In the BAS [38], no relation was found between hypertension and the development of fatal MI, but a relation did exist for the development of clinically unrecognized MI, especially among hypertensives not on medication. Antihypertensive drugs have been shown to reduce new coronary events in the elderly hypertensive population [39–44]. The Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure recommends diuretics or β -blockers as initial drug therapy because these drugs have been demonstrated to reduce cardiovascular morbidity and mortality in controlled clinical trials [35]. The particular antihypertensive agent selected as monotherapy should depend on the associated medical conditions. For example, old individuals with hypertension who have had an MI or who have angina pectoris, myocardial ischemia, or complex ventricular arrhythmias should be treated initially with a β -blocker [44]. Old hypertensive persons with congestive heart failure associated with abnormal or normal left ventricular ejection fraction should receive a diuretic, an angiotensin-converting enzyme (ACE) inhibitor, and a β -blocker [45–53]. Old persons with hypertension who have diabetes mellitus or left ventricular hypertrophy (LVH) should initially be treated with an ACE inhibitor [35, 54].

Old persons with hypertension and a prior MI should be treated with both β -blockers and ACE inhibitors [35, 55–58].

Peripheral Arterial Disease

Numerous studies have demonstrated that hypertension is a risk factor for PAD [10–12, 14–18]. In a study of 1,911 old persons (mean age 81 years), systolic or diastolic hypertension

was observed to increase the prevalence of PAD 2.2 times in men and 2.8 times in women (Table 51.2) [10]. At 43-month follow-up of 291 old subjects with PAD (mean age 82), new coronary events developed in 165 patients (57%) [19].

Hypertension should be adequately controlled to decrease cardiovascular mortality and morbidity in persons with PAD. The blood pressure should be reduced to <140/90 mmHg and to <130/80 mmHg in patients with diabetes mellitus or chronic renal insufficiency, respectively [35, 55]. Among persons with PAD in the Appropriate Blood Pressure Control in Diabetes Trial, the incidence of cardiovascular events in persons treated with antihypertensive drug therapy with enalapril or nisoldipine was 13.6% if the mean blood pressure was reduced to 128/75 mmHg versus 38.7% if the mean blood pressure was reduced to 137/81 mmHg [59].

Atherothrombotic Brain Infarction

Numerous studies have documented that both systolic and diastolic hypertension increase the incidence of stroke in old persons [24, 39–43, 60–62]. Indeed, the higher the systolic or diastolic blood pressure, the greater the incidence of stroke. During a 30-year follow-up of men and women of age 65–94 years in the Framingham Heart Study, systolic blood pressure was the single risk factor most strongly correlated with ABI or transient cerebral ischemic attack [63]. At 42-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, systolic or diastolic hypertension was demonstrated by multivariate analysis to increase the relative risk of ABI 2.2 times in men and 2.4 times in women (Table 51.2) [24].

In the BAS, subjects with measured hypertension had a significantly increased incidence of stroke (1.9/100 person-years) compared with that in controls (0.6/100 person-years) [9]. Previous studies have used a definition of hypertension as systolic blood pressure >160 mmHg, diastolic blood pressure >95 mmHg, or both to show an increased risk of stroke [24, 39–43, 60–62]. The findings in the BAS extended the risk of stroke to this oldest-old age group; [9] and considering the strict study values used, it suggested that the risk exists even

TABLE 51.2 Association of systolic or diastolic hypertension with new coronary events, peripheral arterial disease, and new atherothrombotic brain infarction in elderly men and women

Study	Elderly men			Elderly women		
	No. of patients	Mean follow-up (months)	Relative risk	No. of patients	Mean follow-up (months)	Relative risk
Incidence of new coronary events [6]	664	40	2.0	1,488	48	1.6
Prevalence of PAD [9]	467	–	2.2	1,444	–	2.8
Incidence of new ABI [23]	664	42	2.2	1,488	48	2.4

at levels of blood pressure not previously uniformly considered to be elevated by others. The BAS also showed an association between blood pressure elevation and the risk of vascular dementia [9], suggesting that some dementias could be prevented by blood pressure lowering [64].

Antihypertensive drug therapy has been shown to reduce the incidence of new ABI in old individuals [39–43, 61]. A systolic blood pressure of 140–160 mmHg causes an increased risk for cardiovascular disease that is equivalent to a diastolic blood pressure of 95–105 mmHg [38]. Consequently, the clinician should consider the treatment of old persons with systolic blood pressures in this range. Although nonpharmacologic interventions are indicated [65], there are currently no data showing that drug therapy for systolic blood pressures of 140–160 mmHg reduces the incidence of stroke in old persons. Nevertheless, the presence of LVH, target organ damage, and other risk factors for stroke would cause the authors to treat these individuals with antihypertensive drug therapy [66, 67].

Extracranial Carotid Arterial Disease

Numerous studies have demonstrated by univariate analysis that hypertension is a risk factor for ECAD [25–27, 29, 68]. According to multivariate analysis, however, hypertension is a risk factor in some studies [26, 68] but not in others [25, 26]. In a study of 1,283 old subjects (mean age 81), LVH was more prevalent in those with systolic or diastolic hypertension and ECAD than in those with systolic or diastolic hypertension alone [69].

Left Ventricular Hypertrophy

Coronary Events

LVH caused by hypertension or other cardiovascular disease is not only a marker of but also a contributor to cardiovascular morbidity and mortality in the elderly population. Indeed, old persons with electrocardiographic (ECG) and echocardiographic evidence of LVH have an increased risk of developing new coronary events [7, 70–75].

During a 4-year follow-up of 406 old men and 735 old women in the Framingham Heart Study, echocardiographic LVH was 15.3 times more sensitive for predicting new coronary events in men and 4.3 times more sensitive in women than ECG LVH [73]. The relative risk for new coronary events per 50 g/m increases in LV mass/height was 1.67 and 1.60 for old men and women, respectively [73].

At a 37-month follow-up of 360 old subjects (mean age 82 years) with hypertension or CAD, echocardiographic LVH was 4.3 times more sensitive for predicting new coronary events than ECG LVH [71]. Multivariate analysis of 472 old hypertensive subjects followed for 45 months showed that echocardiographic LVH was an independent risk factor for new coronary events, with a relative risk of 3.2 [75].

In the BAS a multivariate analysis showed that baseline ECG LVH is an independent predictor of MI and overall mortality. Those subjects who developed new LVH on ECG during follow-up had a 3.4 times higher total death rate and a 6.6-fold greater relative risk of cardiovascular death [9].

Atherothrombotic Brain Infarction

Elderly persons with ECG [7, 70–72] and echocardiographic [7, 71, 74–77] LVH have an increased risk of developing a new ABI. During an 8-year follow-up of 447 old men and 783 old women in the Framingham Heart Study, the hazard ratio for new cerebrovascular events was 1.45 for each quartile increase in the LV mass/height ratio after adjustments were made for age, sex, and cardiovascular disease [76]. At the 37-month follow-up of 360 old persons with hypertension and CAD, echocardiographic LVH was 4.0 times more sensitive for predicting a new ABI than ECG LVH [71]. Multivariate analysis of 472 old subjects with hypertension followed for 45 months revealed that echocardiographic LVH was an independent risk factor for a new ABI, with a relative risk of 2.9 [75]. Among 1,482 old persons (mean age 82 years) followed for 45 months, multivariate analysis also showed that echocardiographic LVH was an independent risk factor for a new ABI, with a risk ratio of 2.3 [77].

Physicians should try to prevent LVH from developing or progressing in persons with hypertension or other cardiovascular disease. The effect of various antihypertensive drugs on reducing LV mass is discussed elsewhere [78, 79]. A meta-analysis of 109 treatment studies showed that ACE inhibitors are more effective than other antihypertensive drugs in decreasing LV mass [79].

Reduction of LV mass with antihypertensive agents does not cause deterioration of LV systolic function and may improve LV diastolic function. Data from the Framingham Heart Study have shown a decrease of cardiovascular events in patients with the regression of LVH [80]. In patients with uncomplicated hypertension followed for 10.2 years, the Cornell group found that the development of LVH increases and the regression of LVH decreases the incidence of new cardiovascular events [81]. Regression of ECG LVH by antihypertensive treatment was associated with a 30% significant reduction in sudden cardiac death independently of

treatment modality, blood pressure reduction, prevalent CAD, and other cardiovascular risk factors in hypertensive patients with LVH [82]. In addition, the BAS demonstrated that old subjects who developed new ECG LVH had a higher incidence of cardiovascular morbidity and mortality than old persons without ECG LVH [72] based on a 10-year follow-up. Old persons in whom the ECG pattern of LVH disappeared over time had a lower incidence of cardiovascular morbidity and mortality than old persons with persistent LVH [72].

Dyslipidemia

Serum Total Cholesterol and Coronary Artery Disease

Serum total cholesterol was an independent risk factor for CAD in old men and women in the Framingham Heart Study [83]. Among subjects with prior MI in this study, serum total cholesterol was most strongly related to death from CAD and to all-cause mortality in persons of age ≥ 65 years [84]. Many other studies have demonstrated that a higher serum total cholesterol level is a risk factor for new coronary events in old men and women [2, 6, 85, 86].

During a 9-year follow-up of 350 men and women with a mean age of 79 years, the BAS demonstrated that a consistently elevated low-density lipoprotein (LDL) cholesterol was associated with the development of MI in women [87]. In the Established Populations for Epidemiologic Studies of the Elderly study, serum total cholesterol was a risk factor for CAD-associated mortality in old women but not in old men [88]. At 40-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, there was a 1.12 times higher probability of developing new coronary events in men and women for each 10 mg/dl increase in serum total cholesterol (Table 51.3) [6].

During a 5.4-year median follow-up of 1,021 old men and women with CAD and hypercholesterolemia in the Scandinavian Simvastatin Survival Study (4S), patients treated with simvastatin had a 34% reduction in mortality, a 43% reduction in CAD mortality, a 34% reduction in major coronary events, a 33% reduction in nonfatal MI, a 33% reduction in any acute CAD-related event, a 34% reduction in any atherosclerosis-related endpoint, and a 41% reduction in coronary revascularization [89]. The absolute risk reduction for both all-cause mortality and CAD mortality was approximately twice as great in older persons as in those younger than 65 years of age.

In the Cholesterol and Recurrent Events (CARE) Trial, 4,159 men and women with MI, serum total cholesterol levels

^aFor an increment of 10 mg/dl of serum total cholesterol

^bFor a decrement of 10 mg/dl of serum HDL cholesterol

^cFor an increment of 10 mg/dl of serum triglycerides

<240 mg/dl, and serum LDL cholesterol ≥ 115 mg/dl were followed over a 5-year period [90]. The trial showed a 27% reduction in major coronary events in subjects 60–75 years of age who were randomized to pravastatin at study event; a 20% reduction in major coronary events was observed in subjects <60 years of age who were randomized to pravastatin. Furthermore, the reduction in coronary events was greater in women (46%) than in men (20%). On the basis of these data, old men and women with CAD and elevated total or LDL cholesterol should be treated with a statin drug.

At 6.1-year mean follow-up of 9,014 men and women (3,514 of whom were aged 65–75 years) with MI (64%) or unstable angina pectoris (36%) and serum total cholesterol levels of 155–271 mg/dl in the Long-Term Intervention With Pravastatin in Ischemic Disease Study (LIPID), compared with placebo, pravastatin 40 mg daily significantly reduced all-cause mortality by 22%, death from CAD by 24%, fatal and nonfatal MI by 29%, death from cardiovascular disease by 25%, need for coronary artery bypass surgery by 22%, need for coronary angioplasty by 19%, hospitalization for unstable angina pectoris by 12%, and stroke by 19% [91]. The absolute benefits of treatment with pravastatin were greater in groups of persons at higher absolute risk for a major coronary event such as older persons, those with a higher serum LDL-cholesterol level, those with a lower serum high-density lipoprotein (HDL)-cholesterol level, and those with a history of diabetes mellitus or smoking.

At 5-year follow-up of 20,536 British men and women (10,697 of whom were aged 65–80 years) with either CAD, occlusive arterial disease of non-coronary arteries, diabetes mellitus or treated hypertension and no serum lipid requirement in the Heart Protection Study, compared with placebo, simvastatin 40 mg daily significantly reduced all-cause mortality by 13%, any vascular mortality by 17%, major coronary events by 27%, any stroke by 25%, any revascularization procedure by 24%, and any major vascular event by 24% [92]. In the 1,263 persons aged 75–80 years at study entry

and 80–85 years at follow-up, any major vascular event was significantly reduced 28% by simvastatin. Lowering serum LDL cholesterol from <116 to <77 mg/dl by simvastatin caused a 25% significant reduction in vascular events.

In the Heart Protection Study, 3,500 persons had initial serum LDL-cholesterol levels <100 mg/dl [92]. Decrease of serum LDL cholesterol from 97 to 65 mg/dl by simvastatin in these persons caused a similar decrease in risk as did treating patients with higher serum LDL-cholesterol levels. The Heart Protection Study Investigators recommended treating persons at high risk for cardiovascular events with statins, regardless of the initial levels of serum lipids, age, or gender [92].

On the basis of these data and other data [92–96], the American College of Cardiology/American Heart Association (ACC/AHA) guidelines [55] and the updated National Cholesterol Education Program III guidelines [97] state that in very high-risk persons, targeting a serum LDL-cholesterol level of <70 mg/dl is a reasonable clinical strategy. When a high-risk person has hypertriglyceridemia or low HDL cholesterol, consideration can be given to combining a fibrate or nicotinic acid with an LDL cholesterol-lowering drug [55, 97].

Serum HDL Cholesterol and Coronary Artery Disease

A low level of serum HDL cholesterol is a risk factor for new coronary events in old men and women [2, 6, 83, 87, 88, 98, 99]. In the Framingham Heart Study [83] and in the Established Populations for Epidemiologic Studies of the Elderly study [88], a low serum HDL was a more powerful predictor of new coronary events than was the total cholesterol.

During a 9-year follow-up of 350 men and women in the BAS, a consistently low HDL-cholesterol level was independently associated with the development of MI, cardiovascular disease, or death in men [87]. At a 40-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, multivariate analysis showed that there was a 1.7 times higher probability of developing new coronary events in men and 1.95 times higher probability in women for each 10 mg/dl decrement in serum HDL cholesterol (Table 51.3) [6].

Serum Triglycerides and Coronary Artery Disease

High-serum triglycerides have been reported to be a risk factor for new coronary events in old women but not in old men [6, 83]. At a 40-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, multivariate analysis showed

that serum triglyceride levels were not a risk factor for new coronary events in the men and were a weak risk factor in the women (Table 51.3) [6].

Serum Lipids and Peripheral Arterial Disease

Some studies have shown an association between increased serum total cholesterol and PAD [10, 11, 14–18, 100, 101] but other studies have not [102]. A low serum HDL-cholesterol level, however, has been shown to be associated with PAD [10, 11, 14–18, 100, 101]. In a study of 559 old men and 1,275 old women (mean age 81 years), an inverse association was found between serum HDL cholesterol and PAD [101]. Multivariate analysis demonstrated a 1.24 times higher probability of having PAD for each 10 mg/dl decrement of serum HDL cholesterol.

Increased serum triglycerides have been associated with PAD in some studies [13, 14] but not in others [10, 11, 100, 101]. In a study of 559 old men and 1,275 old women, serum triglycerides were associated with PAD in both men and women according to univariate analysis but not according to multivariate analysis [101].

Treatment of hypercholesterolemia with statins has been demonstrated to reduce the incidence of cardiovascular events and mortality in older persons with PAD [92, 103]. Three double-blind, randomized, placebo-controlled studies have also demonstrated that statins improve walking performance in persons with PAD [104–106].

Serum Lipids and Atherothrombotic Brain Infarction

The Framingham Study found that serum total and HDL-cholesterol levels were not associated with new ABIs in old men or women [107]. However, the serum total cholesterol HDL-cholesterol ratio was associated with new ABIs in the women but not in the men. Very low-density lipoprotein (VLDL) levels were not associated with new ABIs in older men or women [107].

The Multiple Risk Factor Intervention Trial revealed an association between serum total cholesterol and death from nonhemorrhagic stroke in men [108]. Bihari-Varga et al. [109] demonstrated an inverse relation between serum HDL cholesterol and ABIs in men and women. At 42-month follow-up of 664 old men and 48-month follow-up of 1,488 older women, multivariate analysis showed no association between serum lipids and new ABIs in the men. There was an association between serum total cholesterol and an inverse association between HDL cholesterol and new ABIs in the

women (Table 51.3) [24]. In this population, there was a 1.06 times higher probability of developing a new ABI for each 10 mg/dl increment in serum total cholesterol. Likewise, there was a 1.14 times higher probability of developing a new ABI for each 10 mg/dl decrement in serum HDL cholesterol.

In the Scandinavian Simvastatin Survival Study, patients treated with simvastatin had a 27% reduction in new ABIs [89]. In the Cholesterol and Recurrent Events Trial, patients treated with pravastatin had a 31% reduction in new ABIs [90]. A meta-analysis of four primary prevention trials and eight secondary prevention trials of CAD that used simvastatin, pravastatin, or lovastatin to reduce serum total cholesterol levels demonstrated a 27% reduction in new ABIs [110]. Many other studies reported since then have also demonstrated a significant reduction in ischemic stroke in patients treated with statins [91, 92, 111–114].

At 3-year follow-up of 1,410 patients, mean age 81 years, with prior MI and a serum LDL cholesterol of 125 mg/dl or higher, use of statins significantly reduced stroke by 60% [112]. Decreasing serum LDL cholesterol to less than 90 mg/dl was associated with a 7% incidence of new stroke, whereas decreasing serum LDL cholesterol to 90–99 mg/dl was associated with a 16% incidence of new stroke. The lower the serum LDL cholesterol in elderly persons treated with statins, the greater was the reduction in new stroke [112] and in new coronary events [95]. In 4,731 patients, mean age 63 years, with stroke or transient ischemic attack, reduction of serum LDL cholesterol at least 50% by atorvastatin caused a significant reduction in stroke of 31% and in major coronary events of 37% at 4.9-year follow-up [114]. These data support the use of statins to reduce elevated serum total and LDL-cholesterol levels in old men and women to prevent new thrombotic and/or embolic strokes and new coronary events.

A meta-analysis by our group has shown an increased risk of cerebral hemorrhage in patients receiving statins compared with those individuals not receiving statins. The mechanism for this finding is not known, and the data would suggest that patients with a history of cerebral hemorrhage or those individuals with a cerebral hemorrhage on a statin did not receive this therapy for cholesterol lowering [115].

Serum Lipids and Extracranial Carotid Arterial Disease

Elevated serum total cholesterol [25, 116, 117] and decreased serum HDL cholesterol [25, 27, 29, 32, 116, 117] are risk factors for ECAD. In 1,189 persons of age 66–93 years in the Framingham study, there was a strong association between the severity of ECAD and the serum total cholesterol, as measured 8 years before the carotid studies [116]. In women, but not in men, there was a strong inverse association between the severity of ECAD and the serum HDL cholesterol level measured 8 years before the carotid studies and concurrently [116].

In a study of 1,063 old persons, increased total cholesterol and decreased HDL cholesterol, but not serum triglycerides, were found to be risk factors for ECAD [25]. There was a 1.17 times higher probability of having 40–100% ECAD for each 10 mg/dl increment of serum total cholesterol and a 1.66 times higher probability of having 40–100% ECAD for each 10 mg/dl decrement of serum HDL cholesterol. Many studies have demonstrated the beneficial effects of lipid-lowering drug therapy on carotid atherosclerosis and on coronary events [118–121]. At 21-month follow-up of 449 patients with severe carotid arterial disease who did not undergo revascularization, use of statins caused a 87% significant reduction in the incidence of new stroke or new MI or death [121].

Diabetes Mellitus

Coronary Artery Disease

Diabetes mellitus is a risk factor for new coronary events in old men and women [6, 122]. At a 40-month follow-up of 664 old men and 48-month follow-up of 1,488 old women, diabetes mellitus was shown by multivariate analysis to increase the relative risk of new coronary events 1.9 and 1.8 times in men and women, respectively (Table 51.4) [6]. In the BAS diabetes mellitus, by history or a fasting blood glucose level

Prevalence of PAD [9]	467	–	2.4	1,444	–	3.0
Incidence of new ABI [23]	664	42	1.5	1,488	48	1.5
Prevalence of 40–100% ECAD in 1,063 men and women [24]			1.7			

PAD peripheral arterial disease, ABI atherothrombotic brain infarction, ECAD extracranial carotid arterial disease

of >140 mg/dl was associated with an increased incidence risk of all-cause mortality and cardiovascular disease [9].

Diabetic patients are more often obese and have higher serum LDL- and VLDL-cholesterol levels and lower serum HDL-cholesterol levels than do nondiabetics. Diabetics also have a higher prevalence of hypertension and LVH. These risk factors contribute to their higher incidence of new coronary events and new ABIs and the higher prevalence of PAD and ECAD. The drug of choice for treating hypertension in diabetics is an ACE inhibitor or angiotensin receptor blocker [35, 54]. The blood pressure should be lowered to <130/80 mmHg. The serum LDL cholesterol should be reduced to <70 mg/dl by a statin in diabetics [55, 97].

Diabetics with microalbuminuria have more severe angiographic CAD than diabetics without microalbuminuria [123]. Diabetics also have a significant increasing trend of hemoglobin A_{1c} levels over the increasing number of vessels with CAD [124]. Diabetics have a higher prevalence of unrecognized MI and a higher prevalence of silent myocardial ischemia without a history of angina pectoris than nondiabetics [125]. The hemoglobin A_{1c} level should be reduced to <7% in patients with diabetes mellitus [55].

Peripheral Arterial Disease

Diabetes mellitus is a risk factor for PAD in men and women [10–18]. In a study of 467 old men and 1,444 old women, diabetes mellitus was found to increase the prevalence of PAD 2.4 times in men and 3.0 times in women (Table 51.4) [10]. The higher the hemoglobin A_{1c} levels in diabetics with PAD, the higher the prevalence of severe PAD [126].

Atherothrombotic Brain Infarction

Diabetes mellitus is a risk factor for new ABIs in old men and women [23, 107, 127]. At a 42-month follow-up of 664 old men and a 48-month follow-up of 1,488 old women, diabetes was found by multivariate analysis to increase the relative risk for new ABIs 1.5 times in both men and women (Table 51.4) [24].

Extracranial Carotid Arterial Disease

Some studies [25, 128] have shown an association between diabetes mellitus and ECAD, whereas other studies [27] have not. In a study of 1,063 old men and women, diabetes mellitus was demonstrated by multivariate analysis to increase the prevalence of 40–100% ECAD 1.7 times [25].

Obesity

In the Framingham Heart Study, obesity was demonstrated to be a risk factor for new coronary events in old men and women [122]. A disproportionate distribution of fat to the abdomen, as assessed by the waist/hip circumference ratio, has also been shown to be a risk factor for cardiovascular disease, mortality due to CAD, and total mortality [129, 130]. At a 40-month follow-up of 664 old men and a 48-month follow-up of 1,488 old women, obesity was shown to be a risk factor for new coronary events in both men and women by univariate but not multivariate analysis [6].

In the BAS, body surface area was also not predictive. There were no subjects with major obesity problems [9]. In elderly subjects, maintenance of weight and appetite is a sign of health. Indeed, when old subjects lose weight and have reductions in their cholesterol, it may signify starvation, an occult malignancy, or a major cognitive problem.

The Framingham Heart Study showed that relative weight, according to Metropolitan Life Insurance criteria, was not associated with intermittent claudication in women but was inversely associated with intermittent claudication in men [63]. In a study of 244 old men and 625 old women, obesity did not significantly increase the prevalence of PAD in the men, but it did increase the prevalence of PAD 1.8 times in the women [11].

The Framingham Heart Study showed that relative weight was not a risk factor for new ABIs in old men but was a weak risk factor in old women [107]. Barrett-Connor and Khaw [127] observed no association between body mass index and new ABIs in old men and women. At a 42-month follow-up of 664 old men, obesity was not a risk factor for new ABIs [24]. At a 48-month follow-up of 1,488 old women, obesity was a risk factor for new ABIs by univariate analysis but not multivariate analysis [24]. Obesity is not a risk factor for ECAD [23, 27].

Physical Inactivity

Physical inactivity is associated with obesity, hypertension, dyslipidemia, and hyperglycemia. Paffenbarger et al. [131] found that individuals of age 65–79 years with a physical activity index >2,000 kcal/week have a better survival rate than those with an index <2,000 kcal/week. Wenger [132] discussed physiologic bases for the decrease in habitual physical activity with age and noted studies suggesting that physical activity is beneficial in preventing CAD. The relation of physical inactivity to ABI is unclear [107, 133].

Moderate exercise programs suitable for old persons include walking, climbing stairs, swimming, and bicycling.

TABLE 51.5 Association of gender with incidence of new coronary events, prevalence of peripheral arterial disease, incidence of new thromboembolic stroke, and prevalence of 40–100% extracranial carotid arterial disease in old men and women

Study	Old men			Old women		
	No. of patients	Mean follow-up (months)	Incidence or prevalence (%)	No. of patients	Mean follow-up (months)	Incidence or prevalence (%)
Incidence of new coronary events [135]	1,160	46	46	2,464	46	44
Prevalence of peripheral arterial disease [135]	1,160	–	32*	2,464	–	26
Incidence of new thromboembolic stroke [135]	644	46	23	2,464	46	21
Prevalence of 40–100% ECAD [24]	435	–	18	1,057	–	15

ECAD extracranial carotid arterial disease

* $p=0.0001$

Exercise training programs are not only beneficial for preventing CAD [132], but have also been demonstrated to improve endurance and functional capacity in old men with CAD [134].

Age

The incidence of new coronary events increases with age in old men and women [6, 122]. The incidence of PAD [10, 63] and ABI [24, 107] also increased with age. In the BAS, age was the strongest independent predictor of total mortality, cardiovascular mortality, MI, stroke, and dementia [9].

Gender

At a 46-month follow-up of 1,160 old men (mean age 80 years) and of 2,464 old women (mean age 81 years), the incidence of new coronary events was not significantly different in the men (46%) and the women (44%) (Table 51.5) [135]. The prevalence of PAD in the old men (32%) was higher than in the old women (26%) ($p=0.0001$) (Table 51.5). The incidence of new thromboembolic stroke was not significantly different between the men (23%) than in the women (21%) (Table 51.5) [135]. The prevalence of 40–100% ECAD was not significantly different for 435 old men (18%) and 1,057 old women (15%) with a mean age of 82 years. In the BAS, the incidence of MI was higher in women than in men [9].

Race

Black men are 2.5 times more likely to die of stroke than white men, and black women are 2.4 times more likely to die of stroke than white women [136]. Table 51.6 shows the

prevalence of CAD, PAD, and ABI in 268 elderly Blacks (mean age 81), 71 elderly Hispanics (mean age 81), and 1,310 elderly Whites (mean age 82) [137]. The prevalence of CAD was not significantly different among the Blacks, Hispanics, and Whites. However, the prevalence of PAD was significantly higher in the Blacks than in Whites. Likewise, the prevalence of ABI was significantly higher in the Blacks than in either Hispanics or Whites.

Prior Coronary Artery Disease, Peripheral Arterial Disease, and Atherothrombotic Brain Infarction

At a 40-month follow-up of 664 old men and a 48-month follow-up of 1,488 old women, prior CAD was shown by multivariate analysis to increase the relative risk of new coronary events 1.7 times in men and 1.9 times in women [6]. At a 43-month follow-up of 291 old persons (mean age 82) with PAD, prior CAD was shown to be an independent risk factor for new coronary events, with a relative risk of 2.7 [19].

In the BAS, over an average range of 5–8 years of follow-up, the incidences of cardiovascular disease and mortality in subjects with evidence of infarct at baseline were 8.8 and 5.9 per 100 person-years versus 4.7 and 3.9 per 100 person-years in controls, respectively. The rates of development of unrecognized MI (Q-wave) were 2.4 and 3.2 per 100 person-years, respectively, for recognized MI. The rate of development of either a recognized or unrecognized MI was three times more likely in those with a history of a prior infarct [9].

Old persons with prior ABI or transient cerebral ischemic attacks have a higher incidence of ABI [7, 24, 138]. At a 42-month follow-up of 664 old men and a 48-month follow-up of 1,488 old women, multivariate analysis showed that a prior ABI increased the relative risk of a new ABI 2.6 times in men and 2.9 times in women [24].

TABLE 51.6 Prevalence of coronary artery disease, peripheral arterial disease, and atherothrombotic brain infarction in elderly Blacks, Hispanics, and Whites

Disorder	Prevalence (%)		
	Blacks (<i>n</i> =268)	Hispanics (<i>n</i> =71)	Whites (<i>n</i> =1,310)
CAD	46	34	41

Coexistence of Coronary Artery Disease, Peripheral Arterial Disease, and Atherothrombotic Brain Infarction

Persons with PAD [15, 19, 139–143] or cerebrovascular disease [144–146] are at increased risk for developing new coronary events. The Framingham Heart Study demonstrated that the age-adjusted incidence of stroke was more than doubled in patients with CAD [107]. In a study of 110 old persons (mean age 82) with chronic atrial fibrillation, logistic regression analysis revealed that a prior MI was an independent predictor of thromboembolic stroke, with an odds ratio of 4.8 [147].

Table 51.7 shows the prevalence of coexistence of CAD, PAD, and ABI in a study of 1,886 old persons (580 men and 1,306 women) whose mean age was 81 years [148]. If CAD was present, 33% had coexistent PAD and 32% had coexistent ABI. If PAD was present, 58% had coexistent CAD and 34% had coexistent ABI. If ABI was present, 53% had coexistent CAD and 33% had coexistent PAD.

Table 51.8 shows the prevalence of coexistence of CAD, PAD, and ischemic stroke in a study of 1,802 old persons (474 men and 1,328 women) whose mean age was 80 years [149]. If CAD was present, 26% had coexistent PAD and 32% had coexistent ischemic stroke. If PAD was present, 68% had coexistent CAD and 42% had coexistent ischemic stroke. If ischemic stroke was present, 56% had coexistent CAD and 28% had coexistent PAD.

Conclusion

Many of the risk factors and markers for atherosclerosis complicated by CAD, cerebrovascular disease, and PAD seen during middle age continue to be operative in the elderly (Table 51.9) [9].

TABLE 51.7 Prevalence of coexistence of coronary artery disease, peripheral arterial disease, and atherothrombotic brain infarction in 1,886 elderly persons

TABLE 51.9 Factors associated with increased independent risk of incident morbidity or cardiovascular disease in the oldest old^a: Bronx Longitudinal Aging Study

Age
Smoking history
Diabetes mellitus
History of past MI (clinically apparent or silent) documented on ECG
LVH by ECG (including new onset)
Cardiomegaly by chest radiography (including new onset)
Nonsustained ventricular tachycardia on 24-h Holter ECG
Persistent HDL cholesterol ≤30 mg/dl in men; persistent LDL cholesterol ≥171 mg/dl in women
Hypertension, both combined systolic and diastolic and isolated systolic
Prolongation of the RR interval on resting ECG
Nonspecific ST and T-wave abnormalities on resting ECG (unrelated to LV or past MI)
Digoxin use
Unfavorable baseline self-rated health assessment
Development of dementia
High vitamin B ₁₂ level
MI myocardial infarction, ECG electrocardiography, LVH left ventricular hypertrophy

Chapter 52

Cardiac Surgery in the Elderly

Margarita T. Camacho and Pooja R. Raval

As the elderly population steadily rises each year, so does the number of patients referred for cardiac surgical procedures. The U.S. Census Bureau predicted that there would be approximately 7.4 million people over the age of 80 by 2008, as compared to 6.2 million in 2000 [1]. Recent data reported that elderly patients over the age of 70 with no functional limitations could expect to live 14.3 years longer, compared with 11.6 years for those with limitation in at least one activity of daily living [2]. A formidable challenge facing cardiologists and cardiac surgeons is the appropriate treatment of the 40% of a growing elderly population that suffers from symptomatic cardiovascular disease [3]. The morbidity and mortality associated with cardiac surgical procedures in the elderly has substantially decreased since the late 1980s [4], although it is still higher than that of younger counterparts less than 70 years of age [5]. Reports of acceptable mortality rates and improved long-term quality of life justify cardiac operations in most symptomatic elderly patients. Only recently large studies have focused on risk analyses and outcomes in an effort to provide the clinician with as much evidence-based literature as possible to make the most appropriate decisions for many of these complex elderly patients.

Characteristics of the Elderly Cardiac Surgery Population

Despite the lack of consensus regarding the definition of “elderly,” the perioperative cardiac surgery mortality rates rise significantly in patients older than 75 years of age [6]. An individual older than age 80 has more than three times the risk of death after coronary artery bypass than does a

similar 50-year-old patient [7]. The increased risks of death and major complications are due not only to the natural processes of aging that result in associated comorbidities, but also to the fact that cardiovascular disease, the major cause of death and disability among elderly patients, is diagnosed at a more advanced state in this old population.

The aging process is influenced by a variety of genetic and environmental factors and occurs at somewhat different rates in every individual. The older the patient, the more likely is the presence of multiple chronic noncardiac diseases, increased tissue fragility, and limited organ reserves for stressful events [7]. Postoperative complications such as pneumonia, renal failure, stroke, and dementia are more prevalent and contribute significantly to perioperative morbidity and mortality. More than 50% of elderly individuals have at least one or more chronic medical conditions [8]. In addition to the routine preoperative assessment, other issues that must be evaluated include the degree of cognitive, neurologic, renal, respiratory, and immune impairment and the presence of other noncoronary atherosclerosis. Approximately one in three patients older than age 80 has some degree of cognitive dysfunction [9], and it is important to establish a baseline level of performance prior to surgical intervention [10]. Tests with age-specific normative standards include the Wechsler Adult Intelligence Scale, the Controlled Oral Word Association, and the Multilingual Aphasia Examination [11]. Patients with previously compromised cognitive function are at highest risk for such postoperative complications as delirium and progressive cognitive dysfunction. Depression is a common problem in patients of all ages and has been reported to follow cardiac surgery. It is clearly more pronounced in the elderly patient who may live alone and have few social support systems.

By age 80, there is a 25% decrease in kidney mass and 40% reduction in glomerular filtration rate (GFR) [10]. Due to the decrease in lean muscle mass, a decrease in GFR may not be reflected by an increase in serum creatinine concentration, and therefore a “normal” creatinine level in an octogenarian may be misleading. A more useful assessment of renal

function in the elderly patient is the age-related creatinine clearance (Ccr)

$$\text{Ccr (ml/min)} = \frac{(140 - \text{Age}) \times (\text{Ideal body weight in kilograms})}{72 \times \text{Serum creatinine}},$$

where normal is 75–125 ml/min. Renal function should be evaluated both before and after cardiac catheterization, and the amount of renally excreted dye used during angiography should be kept to an absolute minimum, employing nonionic contrast materials. The transient episodes of hypotension that inevitably occur during cardiopulmonary bypass may worsen any preexisting renal dysfunction; in this age group, perioperative renal insufficiency is a strong positive predictor of postoperative mortality [6, 12–14].

Old patients have declining cellular immunity and are therefore more predisposed to developing invasive bacterial and viral infections [10]. In addition to the bacterial colonization of the respiratory, urinary, and gastrointestinal tracts, there is a risk of infection from other monitoring lines and catheters used during cardiac surgery, such as central lines, Swan–Ganz catheters, and mediastinal drainage tubes. Leukocytosis is frequently absent or depressed in an elderly patient, who otherwise commonly exhibits atypical signs of infection such as hypothermia or confusion. Although most cardiac surgery patients are not cachexic or nutritionally depleted owing to their cardiac disease, it is important to assess the preoperative nutritional status of an elderly individual whose other organ reserves are already limited. Adequate nutrition is vital for wound healing and for avoiding infection and ventilatory dependence. Ideally, the serum albumin concentration should be >3.5 mg/dl, and there should be no history of recent significant (>5%) weight loss.

Numerous physiologic changes affect the cardiovascular system with advancing age. There is a decrease in vascular elasticity: The aorta and large arteries become much less compliant, resulting in an increase in peripheral vascular resistance. Left ventricular stiffness is increased [15], as is the ventricular septal thickness [16], and may require higher filling pressures to maintain adequate forward flow. During exercise there is a decrease in peak heart rate and ejection fraction, likely due to reduced responsiveness to circulating catecholamines [17–19]. Autopsy studies of octogenarians revealed that atherosclerotic heart disease with more than 75% narrowing in at least one major coronary vessel was the most common abnormality (present in 60% of patients). In fact, coronary disease was the most common single cause of death, with the most frequent manifestation being acute myocardial infarction [16]. Finally, compared with younger age groups, the heart of the elderly individual has smaller ventricular cavities and tortuous coronary arteries [20–22].

In light of these morphologic findings, it is not surprising that by age 80 at least 20% of this population have an established clinical diagnosis of coronary artery disease, and that eventually 67% of elderly patients die from this disease.

Elderly patients tend to have more advanced coronary artery disease than their younger counterparts by the time they are referred for cardiac surgery. Compared with the Coronary Artery Surgery Study (CASS) with a patient population of mean age 68 years [23], octogenarians were found to have a higher incidence of three-vessel coronary disease (87% vs. 61%; $p < 0.05$), left main or left main-equivalent disease (50% vs. 3%, $p < 0.0001$), and significant left ventricular dysfunction (19% vs. 4% had an ejection fraction <35%, $p < 0.01$) [24]. Older patients are more symptomatic on presentation; many series report that more than 90% of octogenarians are New York Heart Association (NYHA) functional class III–IV preoperatively [13, 25–31]. When compared with younger patients, a significantly higher percentage of elderly patients are referred for more urgent or emergent procedures, which carry substantially increased risks of major morbidity and mortality [7, 13, 24, 29, 31–34]. This underscores the need to prevent emergent and urgent surgical interventions.

A common finding in elderly patients is calcification and intimal disease of the aorta, which can crack and embolize when the ascending aorta is clamped or manipulated during cardiac operations. Such embolization to cerebral vessels is the principal cause of perioperative stroke in this age group [35]. Other causes of surgery-related neurologic deficits include transient episodes of systemic hypotension during cardiopulmonary bypass and air embolism from procedures that necessitate opening cardiac chambers or great vessels, such as aortic or mitral valve operations. Although aortic valve calcification is present in more than 55% of patients over the age of 90, only 5% eventually develop significant hemodynamic valvular stenosis [36]. One important difference between aortic and mitral valve disorders in the elderly is that aortic valve disease is usually associated with preserved left ventricular function, whereas mitral valve disease in the elderly is often ischemic in nature and is associated with significant ventricular dysfunction. Davis et al. [37] noted that only 29% of elderly patients with significant aortic valve disease had concomitant disease of two or more coronary vessels, compared with 46% of patients with significant mitral valve disease.

Predictors of Perioperative Morbidity and Mortality

As experience with the surgical treatment of cardiac disease in septuagenarians has grown, the literature has focused on the surgical outcome in octogenarians (Table 52.1). Many of these studies have reported predictors of perioperative morbidity

TABLE 52.1 Cardiac surgical procedures in the octogenarian: results and average length of hospital stay

Study	Year	No.	Procedure	Mortality (%)	Complication rate (%)	Mean postoperative LOS	% Survival (years)

Rich et al. [47]	1985	25	Mixed	4	92	19.5	84 (2)

Mixed series includes valve and coronary bypass procedures and/or valve+coronary bypass procedures; *AVR* aortic valve replacement, *CABG* coronary artery bypass grafting, *LOS* length of stay in hospital

and mortality based on extensive univariate and multivariate analyses. This information has proved vital in identifying specific factors that may be optimized preoperatively and has provided physicians and patients with the ability to make timely treatment decisions based on expected short-term and long-term outcomes.

Several studies have shown that a decreased ejection fraction is a significant predictor of hospital mortality following cardiac surgery. This is even more predictive of an adverse outcome in octogenarians. A number of series have reported hospital mortality rates of 3–6, 5–13, and 24–43% in patients with normal, moderately impaired, and severely impaired (ejection fraction < 0.30) left ventricular function, respectively [48–50]. In a multivariate analysis of factors involving 159 octogenarians who underwent isolated coronary artery bypass, Mullany et al. [44] found that an ejection fraction less than 0.50% was the most important predictor of adverse survival ($p < 0.01$). Ko and coworkers, who analyzed 100 consecutive octogenarians undergoing isolated coronary artery bypass, also found a decreased ejection fraction to be the most significant predictor of perioperative mortality ($p < 0.002$). In fact, an ejection fraction less than 30% was associated with a mortality rate of 43% [28].

High NYHA functional cardiac class was highly predictive of hospital mortality in numerous studies [13, 16, 19, 22, 25, 26, 31, 45]. In their series of 76 octogenarians undergoing a variety of cardiac surgery procedures, Tsai et al. [48] found that 94% of the hospital deaths were in patients who presented in NYHA functional class IV. In a study of 24,461 patients 80 years and older who underwent isolated coronary artery bypass, measures of more acute coronary disease, such as acute myocardial infarction (MI) before bypass surgery, predicted higher procedural and long-term mortality rates [49]. This relation with acute coronary artery disease has been borne out by numerous other authors [24, 26, 28].

Combined coronary surgery procedures and mitral valve replacement (MVR) have been shown to carry significantly higher hospital mortality rates in the elderly population [19, 27, 32, 36, 37, 39, 42, 45]. In the early 1990s, Davis and coworkers reported operative mortality rates of 5.3% for aortic valve replacement (AVR), 20.4% for MVR, and 5.8% for isolated coronary artery bypass [37]. Several years earlier, Naunheim et al. reported even higher hospital mortality rates of 50% for MVR, 9% for AVR, and 67% for double valve replacement combined with coronary revascularization [33]. More recent outcomes for those aged 75

and above at Newark Beth Israel Medical Center, a participant in The Society of Thoracic Surgeons 2004–2008 database, reveal mortality rates of only 4.8% for isolated AVR, 0% for isolated MVR, and 3.0% for isolated CABG (personal communication).

The outcome after valve replacement in elderly patients is primarily a function of the myocardial performance, which decreases as the severity of any associated coronary artery disease increases. Old patients undergoing AVR tend to have a well-functioning ventricle; the degree of coronary artery disease tends to be less than that in patients undergoing MVR. Patients requiring mitral valve surgery tend to have more serious ischemic disease, which can irreversibly damage the myocardium and result in higher perioperative mortality [20–22, 27]. Furthermore, combined procedures require longer cardiopulmonary bypass times and longer ischemic cross-clamp times, two factors that are predictors of operative mortality as well [19, 24, 26, 28].

In addition to presenting with more advanced disease than their younger counterparts, a higher percentage of octogenarians are referred for urgent or emergent surgical intervention. As noted in Table 52.2, urgent and emergent operations are associated with extremely high mortality rates, particularly if a mitral valve procedure is performed independently or in combination with other procedures. These increased mortality rates reflect the progression and severity of the cardiac disease and the lack of functional reserve for stressful events in this older population. Another related factor, preoperative hemodynamic instability, was described by several authors as the need for an intra-aortic balloon pump (IABP) [15, 19, 24, 25, 33, 39], preoperative admission to the coronary care unit [34, 38, 44], and preoperative use of inotropes and vasoactive medications [33, 50]. Each was found to be a significant predictor of hospital mortality. Multivariate analyses by Williams and coworkers, who studied a group of 300 octogenarians who underwent isolated coronary artery bypass, revealed that preoperative renal dysfunction (creatinine > 2.0 mg/dl), pulmonary insufficiency, and postoperative sternal wound infection were strong predictors of hospital mortality [13]. Tsai and coworkers found that 67% of the elderly patients with postoperative mediastinal bleeding necessitating reoperation ultimately died [48].

FIGURE 52.1 Effect of advanced age on the predicted probability of neurologic and cardiac morbidity (from Tuman et al. [51], with permission).

In a prospective study of 2,000 patients undergoing coronary artery bypass, Tuman et al. [51] studied the effect of age on neurologic outcome. The rate of neurologic complications rose significantly with age; patients <65 years old had a 0.9% stroke rate, whereas those aged 65–74 and >75 had rates of 3.6 and 8.9%, respectively ($p=0.0005$). Suspected causes of serious neurologic events (in patients unresponsive for more than 10 days) include atheromatous emboli from the ascending aorta, hypotension or low-flow state during cardiopulmonary bypass, and preexisting critical extracranial or intracranial cerebrovascular disease. The mortality rate in this group of patients who sustained significant strokes was 74% (Fig. 52.1) [51]. Perioperative mortality associated with perioperative stroke in younger patients, although still formidable, was less than half of this frequency (24–26%).

Quality of Life

Although the short-term and intermediate-term survival for elderly patients undergoing cardiac surgery is somewhat less than their younger cohorts, the long-term survival for

octogenarians after open heart surgery compares favorably with survival for the general US population of similar age. In a series of 600 consecutive patients 80 years or older undergoing various open heart procedures, the 5-year actuarial survival, including hospital mortality, was $63 \pm 2\%$. Survival in this group was identical to that for the simultaneous general US octogenarian population [14]. Excellent long-term results have been achieved by several groups in octogenarians after mitral valve surgery, aortic valve surgery, and coronary artery bypass surgery [40, 52, 53].

Of as great importance to the elderly as survival is the associated quality of life. Several authors have shown that most (81–93%) of the octogenarians who survive open heart surgery “feel” as good and frequently better than before their operations [14, 29, 40, 53]. An equally high percentage (75–84%) of octogenarians believed in retrospect that having decided to have a cardiac surgical procedure after age 80 had been a good choice [14, 54]. The precise and objective measurements of quality of life may be difficult to quantify. Based on well-studied populations, it has been possible to construct instruments that reliably assess the various domains of daily living, thereby producing a meaningful reproducible measurement of quality of life [55–57].

The NYHA angina functional class and cardiac failure functional class reflect symptom-free living with regard to chest pain and dyspnea. Octogenarians have consistently demonstrated substantial improvement in their NYHA angina functional class and cardiac failure functional class after open heart surgery. In several reports, most (68–92%) of the octogenarians who survived open heart surgery were in NYHA functional class I or II during long-term follow-up. This improvement was seen after isolated coronary artery bypass operations, valve operations, and combined operations (Table 52.3). When a well-validated health care index, the SF-36, was employed to study prospectively a cohort of elderly and nonelderly patients, those over 75 years of age enjoyed an identical long-term improvement in each of the seven domains of the SF-36. Indeed, as many of the elderly patients had low quality of life SF-36 scores preoperatively as their younger cohorts, their improvements were even greater, as both populations ended up with statistically identical SF-36 scores 6 months following surgery. Any neurologic injury associated with the diagnostic and surgical process dramatically affected their quality of life adversely when compared with those old patients who did not suffer any neurologic injury.

Many octogenarian patients live alone and consequently have impaired ability to carry out activities of daily living, which places them at a significant disadvantage. Karnofsky dependency category (KDC) and social support index (SSI) reflect the degree of help needed by patients. Glower and coworkers, using the KDC, showed that the median performance status in a group of octogenarians undergoing isolated coronary artery bypass

FC functional class

grafting improved from 20% preoperatively to 70% at hospital discharge, with 89% of survivors being discharged home [26]. Kumar et al. showed that when there was a significant decrease in the level of social support needed by octogenarians after open heart surgery, the mean KDC and mean SSI decreased significantly at the short-term follow-up (less than 2 years) [54]. These improvements were also present but significantly less evident at the long-term follow-up (more than 5 years). It is likely that significant comorbid conditions limit the ability of octogenarians to live independently long term, although they remain symptom-free from a cardiac point of view and do well in the short term.

As mentioned above, the subjective indicators of quality of life for octogenarians after open heart surgery are complex and involve a number of modalities relating to various domains of life. In the study by Kumar et al., indices for satisfaction with marriage, children, and overall life, feelings

about the present life, and general affect were assessed. In the short term, the indices for satisfaction with overall life and eight bipolar items assessing general affect showed significant improvements, although all these improvements became less evident at long-term follow-up [54]. Perhaps the symptomatic benefits and the value of cardiac surgery as seen subjectively by the patients lie in the question, "Would you choose to undergo cardiac surgery again?" Virtually all the current studies in the literature have shown that most octogenarians would have made the same decision to undergo open heart surgery retrospectively.

Possible Strategies to Decrease Operative Risk

Improvements in surgical techniques and anesthesia have increased the confidence of cardiac surgeons performing operations on an elderly population with increased perioperative risk. Awareness of the problems unique to this growing population of elderly patients, along with recent statistical data highlighting the impact of these problems on morbidity and mortality, can help the medical team recommend the most appropriate treatment choice and timing of intervention in each individual case.

The two principal causes of perioperative cerebrovascular accidents (CVAs) in elderly patients undergoing cardiac surgery are embolization (air, atheroma, and calcific debris) and hypotension resulting in inadequate perfusion of the central nervous system. Preoperative evaluation of the ascending aorta and carotid arteries and intraoperative assessment of the proximal aorta using transesophageal or epi-aortic echocardiography may alter the conduct of the procedure, minimize intraoperative manipulation, and thereby significantly reduce the incidence of stroke [34, 35, 39, 51, 61]. Such information enables the surgeon to avoid cannulation or direct manipulation of heavily diseased portions of the aorta where atheromas may dislodge or where plaque disruption may cause aortic dissection. The presence of extensive atheromatous or calcific disease, which precludes safe manipulation of the ascending aorta in patients with advanced coronary disease, leaves the surgeon with several choices.

1. Abandon the surgical procedure and consider nonoperative or nonbypass revascularization, such as angioplasty, transmyocardial revascularization, or angiogenesis.
2. Perform surgical revascularization on a beating heart, using one or both internal thoracic arteries or nonaortic-based grafts.
3. Establish cardiopulmonary bypass via the femoral, axillary, or other systemic nondiseased artery and perform graft replacement or endarterectomy of the ascending

aorta [34, 35]. The latter alternative is an aggressive, complex procedure and in the elderly population it should be reserved for the very good risk patient with no significant comorbidities.

Diffuse systemic atherosclerosis is more prevalent in the elderly than in younger patients; as such, special precautions should be taken to ensure adequate cerebral and renal perfusion perioperatively. Maintaining high perfusion pressures while on cardiopulmonary bypass can help decrease the incidence of ischemic stroke [62, 63]. Control of atrial arrhythmias and avoidance of episodes of sustained arterial hypotension due to hypovolemia or medications are important during the immediate postoperative period. Although there is still controversy regarding the management of asymptomatic carotid disease, it is believed that known carotid disease in the elderly population is a risk factor for postoperative CVA [14, 34, 44, 51]. Morris et al. [25] recommended routine preoperative assessment of carotid artery disease in octogenarians and advocated carotid endarterectomy if significant disease is found. If symptomatic carotid artery disease is diagnosed prior to cardiac surgical intervention, consideration should be given to performing a staged or a combined procedure. If asymptomatic significant carotid disease is discovered by Doppler preoperatively (>75% stenosis bilaterally or lesser degrees of unilateral stenosis in the presence of an occluded contralateral artery), concomitant carotid endarterectomy may decrease the risk of perioperative stroke [61].

Because of the significant increase in mortality associated with urgent or emergent operative procedures (Table 52.2), all possible measures must be taken to optimize the elderly patient preoperatively and possibly convert an urgent or emergent situation to a more elective one. Careful selection of elderly patients in this setting is critical, and one must evaluate the patient's mental status and existing comorbidities when determining the potential for meaningful survival before recommending operation. Aggressive preoperative medical management includes the use, when necessary, of intravenous nitroglycerin or heparin (or both), inotropic and ventilatory support, and if absolutely necessary, the IABP. Although numerous studies have reported that preoperative use of the IABP is a significant predictor of perioperative mortality [12, 14, 33, 50], it likely reflects the severity of the elderly patient's underlying cardiac disease, rather than any inherent risk in using the device. Sisto et al. [64] reported that in 25 consecutive octogenarians requiring IABP insertion, there were no significant complications related to device insertion; and of 20 patients who eventually underwent surgery after IABP, only two patients (10%) died in hospital. This operative mortality rate is significantly better than that reported by others for urgent/emergent cases (Table 52.2).

There is a strong association between early postoperative death and prolonged ventilatory dependence [60], which can

develop quickly in the elderly patient. As soon as the patient awakens from general anesthesia, respiratory muscles must be exercised. Pulmonary hygiene and physiotherapy must be aggressive with early and progressive ambulation. Unlike their younger counterparts, elderly patients have much less functional reserve, and therefore a successful first attempt at extubation and mobilization ensures the best outcome. Intraoperatively, exquisite care must be taken to avoid injury to the phrenic nerve during harvesting of the internal thoracic artery, and use of bilateral internal thoracic arteries should generally be avoided [65].

Nephrotoxic drugs should be avoided; or, if necessary, doses should be adjusted in light of the decreased renal function in elderly patients. Intravenous renal dosage dopamine hydrochloride (1–2 µg/kg/min) may have benefit when used for any patient with preexisting renal insufficiency. Because of the high mortality associated with perioperative renal failure in this population [13, 38, 43, 66, 67], an aggressive approach to optimize preoperative renal function is essential. Although rigorous studies demonstrating the benefit of “renal dopamine” are inconclusive, many centers use this drug to enhance urine flow during and immediately after cardiac surgery.

Cognitive function is one of the most important factors affecting overall outcome and is one of the most difficult neurologic outcome parameters to measure and assess. Delirium and confusion are common in the postoperative elderly individual and can hinder important initial attempts to extubate and mobilize a patient. Encephalopathy changes are seen in as many as 30% of all bypass patients and 50% of elderly patients. Sensory deficits such as those due to hearing or vision impairments can be addressed as soon as the patient awakens by providing hearing aids and eyeglasses. Invasive lines and monitoring equipment should be removed as soon as the patient is medically possible to facilitate mobilization. Transfer out of an intensive care unit (ICU) setting, when possible, helps restore the sleep–wake cycle. Family members should stay with confused patients to offer reassurance and encouragement. Long-acting benzodiazepines should be avoided or other sedative/hypnotic medications altered to prevent excessive sedation, confusion, and respiratory depression. Haloperidol is a more appropriate drug for the management of delirium in this patient population because of its short-acting effect and safety margin in the postoperative cardiothoracic patient. Small doses are usually effective, and the patient can be rapidly weaned in conjunction with professional and family encouragement.

Octogenarians are more likely to develop sternal dehiscence due to osteoporosis of the sternum. The use of bilateral internal thoracic arteries should be avoided. Sternal wound infection has been shown to be a positive predictor of mortality in this group of patients [13].

Aggressive management is essential and includes early institution of intravenous antibiotics, timely debridement, and either primary reconstruction or secondary closure with a wound vacuum device. Adequate nutrition and pulmonary physiotherapy are critical to success. Staged closures are to be avoided in this population, other than for the most advanced infections, which should then undergo coverage and secondary closure as rapidly as possible.

Utley and Leyland described a highly selected group of 25 patients over the age of 80 who underwent coronary artery bypass with no hospital deaths [68]. Patients were selected on the basis of their ability to achieve acceptable functional recovery after operation. All patients were living at home alone or with relatives preoperatively, and they were ambulatory and capable of caring for their own personal needs. They were counseled preoperatively regarding the importance of early ambulation and self-care postoperatively. Four patients were rejected for surgery based on mental or physical senility, previous debilitating strokes, or a history of long-term institutional care. Anesthetic management included the use of short-acting agents and minimal use of postoperative sedation. Patients were extubated within 9–48 h postoperatively, and many were ambulatory and eating on the first postoperative day. Although this restrictive degree of patient selection is not appropriate in most cases, it illustrates how outcome can be strongly influenced by preexisting functional status and meticulous perioperative care.

Nonsurgical Alternatives

During the current era of health care reform, there is considerable interest in providing the most appropriate care for patients more than 80 years of age at an “acceptable” cost [69]. As coronary bypass surgery is the most common major operation performed in the USA (more than 300,000 done annually), the use of coronary bypass in the very elderly is an important issue in the present cost-conscious environment. Medicare data from 1987 to 1990 indicated that the use of this operation in patients more than 80 years of age increased by 67% during that time period [49]. The projected rise in the number of coronary bypass procedures to be done in these patients and associated costs is impressive (Fig. 52.2) [49]. Numerous studies have shown a considerable increase in length of stay (3–4 days longer) and hospital costs (\$3,000–\$6,000 more) in patients over 80 years old versus their younger counterparts. Failure to provide this service, however, often results in repeated and prolonged hospitalization, the need for multidrug therapy, and poorer quality of life, not to mention the emotional impact on patients and their families [7, 49].

In one series of octogenarians, when coronary surgery was compared with medical therapy, the overall cost, annual reinterventions, coronary disease-associated readmissions, and mortality were favored in the surgical group. Several studies have attempted to compare the treatment results of less expensive alternatives to coronary bypass surgery. In elderly patients, percutaneous transluminal coronary angioplasty (PTCA) has the advantages of shorter hospital stay, less immobilization, and lower cost compared with coronary artery bypass; however, coronary bypass confers greater and more durable freedom from angina, less need for future repeat interventional measures, and overall improved quality of life [36, 70, 71]. Although Mick et al. [72] reported that the procedural complication rates in matched groups of patients undergoing coronary bypass versus PTCA were similar, Braunstein et al. [70] observed that PTCA in the setting of unstable angina was associated with high initial morbidity but long-term survival roughly equivalent to that after coronary bypass surgery. As mentioned above, compared with medical noninterventional therapy, coronary artery bypass provides a significant survival advantage and improved quality of life. Ko et al. [71] compared 36 octogenarians who underwent coronary artery bypass with 29 octogenarians who continued medical noninterventional therapy and found that the functional class did not change in the latter group but improved significantly in the former group (NYHA functional class decreased from 3.4 to 1.2, $p < 0.01$). The 3-year survival rate of 77% for the surgical group was similar to the survival of octogenarians in the general US population and was significantly better than that of 55% for the medical group. In summary, coronary bypass surgery provided improved long-term survival and functional benefit compared with medical therapy and improved the quality of life compared with PTCA.

FIGURE 52.2 Projected number of bypass surgery (CABG) procedures performed per year in octogenarians (*left axis*) and the corresponding projected costs for these procedures (in 1990 dollars) (*right axis*) (from Peterson et al. [49], with permission).

The New Era of Mechanical Circulatory Assist

In the mid-1980s, implantable mechanical circulatory assist devices were introduced in FDA clinical trials for patients with severe left ventricular dysfunction who were awaiting transplant and would otherwise not survive without such support. The most popular device in this early era, the HeartMate pneumatic left ventricular assist device (LVAD), enabled patients to ambulate and exercise on treadmills while in-hospital. The advantages of LVAD therapy for the often debilitated, deconditioned patients were significant and resulted in improved outcomes for heart transplant recipients who were able to optimize their physical and physiologic conditions prior to transplant. Since then the LVADs have become smaller (Figs. 52.3 and 52.4), more durable, and associated with increased survival rates when compared with the earlier models [73]. The smaller size and decreased postoperative complications have enabled this technology to be offered to the elderly population with acceptable perioperative risk.

FIGURE 52.3 HeartMate II LVAD (reprinted with permission of Thoratec Corporation).

FIGURE 52.4 Mechanical circulatory support device placement (reprinted with permission of Thoratec Corporation).

The oldest patients with these smaller LVADs are octogenarians who, like their younger counterparts, are leading productive lives outside the hospital.

For a selective group of elderly but active patients who suffer hemodynamic compromise due to severe cardiac dysfunction, a temporary mechanical assist device can be implanted if there is hope of cardiac recovery, such as after a large myocardial infarction. Newer devices in this category, such as the Thoratec CentriMag, have been associated with fewer complications and improved survival (personal communication).

Guidelines for Therapy in the Elderly Cardiac Surgery Patient

During the process of deciding whether to offer cardiac surgical intervention to elderly patients, the relief of symptoms and improvement in quality of life should assume more

importance than the issue of increased life expectancy. When surgical revascularization is considered in this patient population, numerous social, ethical, and clinical issues arise. Comorbidities, quality of life, and concerns raised by the patient's family should be acknowledged and factored into the decision-making process. It is important to integrate the patient's and family's wishes, but one must focus the therapeutic decisions on the patient's advance directives. Emergency cases in these patients may be associated with more than 70% mortality risk, and therefore nonoperative treatment must be strongly considered. Asymptomatic patients should continue medical treatment unless there is critical (>70%) left main coronary artery stenosis, which is associated with significantly reduced life expectancy. Numerous groups (Table 52.2) have observed significantly increased mortality when combined procedures were performed. One study, comparing the operative mortalities for isolated AVR and isolated coronary artery bypass to combined AVR+coronary bypass, demonstrated five- to sixfold increased operative mortality in the combined procedure group [48]. In situations where two or three disease processes exist, the surgical plan should be modified to avoid such increased risks. For example, in an elderly patient with angina, severe coronary artery disease, and noncritical aortic stenosis, coronary revascularization alone may be the best option. Such patients are usually not at risk for a serious morbid event due to their aortic stenosis [36]. Conversely, in a patient with critical aortic stenosis, congestive heart failure, preserved or mildly impaired left ventricular function, and noncritical coronary lesions (<70–80% stenosis), valve replacement alone may be the best alternative. Fiore et al. [46] noted that of the early deaths of patients undergoing combined AVR+coronary bypass, 60% were due to low cardiac output; the patients who had died had little or no angina preoperatively, but each had considerable congestive heart failure and may have been better served by valve replacement alone.

Definitive treatment of isolated aortic stenosis is surgical replacement of the valve, preferably with a bioprosthesis that prevents a lifelong requirement for anticoagulation. The tissue valves have demonstrated impressive freedom from structural deterioration and reoperation at 10 or even 15 years in patients older than 65 years of age. Stentless bioprostheses may have some advantage in elderly small aortic root patients, but long-term benefit and durability remain unproven. Percutaneous balloon valvuloplasty may offer effective initial palliation, but medium- and long-term durability results have been disappointing. Symptoms recurred within 1 year in most patients and necessitated subsequent surgery [74, 75].

Chronic aortic regurgitation may be well tolerated for several decades before congestive heart failure occurs. Once symptoms appear and ventricular dilatation begins, AVR

CASE STUDY: CROSSING THE FRONTIER

Stanley M., an active male in his late 1970s, presented to a local hospital near his home in New Jersey after suffering a large myocardial infarction. Due to hemodynamic instability, he received an IABP, was intubated and transferred to Newark Beth Israel Medical Center for further treatment. Despite high-dose inotropes, he

was not able to be weaned from the IABP and remained intubated. He received an implantable LVAD, the newer and smaller HeartMate II, as part of a clinical trial. He was able to be extubated and weaned from the IABP, and was discharged home to lead an active life that includes travel and caring for his brother. Had this technology not been available to Stanley, he would have expired in the hospital [77].

should be offered before chronic volume overload results in symptomatic irreversible myocardial and pulmonary damage. The most appropriate time to replace the valve is soon after left ventricular dilatation begins.

Surgery is usually recommended for mitral stenosis patients with NYHA functional class II–III heart failure and a calculated mitral valve area less than 1.0 cm². Percutaneous balloon mitral valvuloplasty, unlike the similar treatment for stenotic aortic valves, may be useful when only the mitral valve leaflets are impaired and there is no significant calcification or regurgitation. The subvalvular apparatus should be functional and not destroyed, as can happen with advanced rheumatic valve disease [76]. Mitral valve balloon valvuloplasty usually provides relatively long-term relief of dyspnea but is frequently not possible in elderly patients with advanced disease and heavily calcified mitral valves. MVR, although the definitive treatment for mitral valve stenosis, carries significantly increased procedural mortality either alone or combined with other procedures in the elderly. Naunheim et al. [33] observed operative risks of 42% for either MVR alone or MVR+coronary bypass. Combined MVR+AVR was associated with a 67% risk of surgical mortality, further suggesting a limited role for MVR in this elderly population. These procedures require prolonged periods of cardiopulmonary bypass and global cardiac ischemia, both of which are poorly tolerated by such patients with limited cardiac and other organ reserve. For these reasons, Fiore et al. [46] recommended that every effort be made to keep such operations simple and expeditious.

In patients with advanced coronary artery disease who may be at high risk for complications arising from cardiopulmonary bypass, such as those with severe calcific disease of the ascending aorta (precluding safe insertion of cannulas), a history of stroke, or end-stage pulmonary or renal failure, an alternate option is surgical revascularization on a beating heart. Technologic advances in pericardial retraction systems and stabilization devices have enabled the surgeon to perform anastomoses on a beating heart with the use of newer

surgical techniques. However, there is a significant learning curve, as the surgical field is not nearly as optimal as that produced by cardiopulmonary bypass and ischemic arrest. Recent reports have observed a failure rate of 10% even in experienced hands. Although a reasonable alternative for patients who would otherwise have no interventional options, the increased risk of technical failure must be kept in mind and discussed with the patient and family.

Finally, for elderly patients in previously good physical and mental condition who suffer from acute or chronic severe ventricular dysfunction, both short-term and long-term mechanical circulatory assist devices are available at an acceptable operative risk, compared with their earlier counterparts.

Conclusions

As the elderly population has grown, so have the number of elderly patients being referred for cardiac surgery and their disease complexity. For the most part, these patients can be offered conventional surgical procedures with acceptable mortality, morbidity, and long-term quality of life expectations. Indeed, the perioperative complications are somewhat more numerous than for younger patients even when they are compared for procedure and matched for other risk factors.

This incremental morbidity and mortality is seen across the entire population but is most pronounced in emergently operated patients. With the availability of new and different techniques to accomplish myocardial revascularization and valvular repair and replacement, and the recent availability of mechanical assist devices, the range of procedures available for elderly patients with hemodynamically important heart disease is increasing at a rate almost faster than the population itself has grown. It is therefore critical that the health care professionals caring for these older patients are aware of ongoing developments in these areas and carefully stratify the preoperative risk factors to best select the least morbid and most effective procedure that is currently available.

Chapter 53 Invited Commentary

Frank J. Veith

The diseases of the vascular system discussed on this section comprise, in the elderly, primarily different manifestations of arteriosclerosis.

Occlusive arterial disease is the result of extensive plaque formation which can itself produce flow reducing arterial stenoses or occlusions. Plaque rupture and associated thrombosis or embolization can worsen the occlusive process.

Several generalities apply to arteriosclerotic occlusive disease. First, although most elderly patients have many arteriosclerotic plaques or lesions, most of these do not need to be treated. There is considerable reserve in the arterial system, so that the occlusive process must be extensive before symptoms occur. Although a single occlusive lesion can cause intermittent claudication, such single lesions in the elderly are often asymptomatic. Furthermore, all invasive treatments, with open surgical or endovascular techniques, are imperfect with frequent early and late failures. Therefore, most patients with occlusive lesions, certainly those who are asymptomatic or have mild symptoms, should not be treated invasively. Conservative treatment with reassurance that their limbs will probably not be threatened is usually best.

Second, more advanced limb threatening ischemia or so called critical limb ischemia (CLI) usually only occurs in patients who have multilevel occlusive disease. Only when this is associated with gangrene, a non-healing ulcer or true ischemic rest pain is aggressive interventional or surgical treatment justified. Such treatment may involve procedures which deal with small crural arteries below the knee, and may be difficult even for highly skilled specialists. Nevertheless, as we have shown for many decades, such aggressive efforts to save threatened limbs are almost always worthwhile even in elderly patients and those with diabetes [1, 2].

Third, patients with critical lower limb ischemia have a limited life expectancy with half of such patients dying within

the first 5 years of their first revascularization procedure [1, 2]. Nevertheless many of these patients will have a failure of their revascularization with a renewed threat to their limb. Redo procedures, either surgical or interventional, usually can salvage the extremity, and have been shown to be worthwhile [1, 2]. Although such procedures can require considerable skill, they are an important part of the care of CLI patients.

Fourth, although surgical bypasses supplemented by catheter based treatments such as balloon angioplasty constituted the mainstay of treatment for arteriosclerotic occlusive disease for many decades, in the last 10–15 years there has been a paradigm shift in the treatment of this entity. Catheter based treatments are becoming the first therapeutic option for most patients requiring treatment for lower limb ischemia. Nevertheless 20–35% of these patients will require an open surgical procedure at some time in the course of their disease [3].

Extracranial cerebrovascular disease is primarily arteriosclerotic disease at the bifurcation of the common carotid artery into its internal and external branches in the neck. Plaques at this location can produce cerebral emboli, which can lead to strokes or transient neurological motor, sensory, or visual symptoms. When such symptoms occur in the absence of other pathology, the plaque is considered symptomatic. Over the last 50 years, carotid endarterectomy (CEA) has become the standard of care for such symptomatic plaques and also for high grade stenotic plaques that have not yet produced symptoms (asymptomatic plaques). More recently carotid artery angioplasty and stenting (CAS) has emerged as an alternate treatment for symptomatic and asymptomatic carotid plaques, and is being promoted and performed more commonly, particularly by interventional cardiologists.

There are three important facts to consider in this area. First, to date, all randomized trials comparing CEA to CAS for symptomatic carotid disease have shown CAS to be inferior to CEA. Second, CAS in elderly patients over 75 years of age has repeatedly been shown to be excessively risky. Although these facts may change as the technology improves, CEA should remain the treatment of choice for symptomatic carotid stenosis patients, particularly the elderly, unless there

F.J. Veith (✉)

Bronx, NY 10471, USA
e-mail: fjvmd@msn.com

are compelling contraindications to a surgical procedure in the neck (radiation, scarring, a tracheostomy, or a high lesion).

Third, medical treatment for asymptomatic carotid stenosis has made dramatic advances in the last decade. Treatment with statins, antiplatelet agents, ACE inhibitors, and better control of blood pressure and diabetes has been shown to alter plaque pathology and behavior, and to dramatically reduce the risk of stroke in arterioclerotic patients. It is therefore likely that few if any asymptomatic patients with carotid stenosis will benefit from either CEA or CAS, although level I evidence to prove this is not available.

Treatment of aneurysms. Although aneurysms can occur anywhere in the arterial tree, this commentary will deal only with those of the abdominal and thoracic aorta (AAA and TAA). Since 1992 and continuing to the present, there has been a paradigm shift in the way.

AAAs and TAAs are being treated. Before 1992, the standard of care for the treatment of AAAs and TAAs that had reached a size that required treatment (5–5.5 cm for AAAs and >6 cm for TAAs) was open surgical exclusion of the aneurysm with a prosthetic polyester graft. Increasingly, over the last 17 years, the standard of care has been shifting to endovascular repair with an endovascular graft or stent-graft. This shift has already occurred for most elective AAAs although a proportion still require open repair for anatomical reasons. This proportion is shrinking as better technology, particularly branched endografts, becomes available. The shift

to endovascular repair is also occurring for many TAAs and most ruptured AAAs [4].

Unlike CEA versus CAS where the differences in morbidity between the open and endovascular procedures are minimal, the differences between open and endovascular repair of abdominal and thoracic aneurysms are substantial. Because of this morbidity differential, it is likely that endovascular procedures will ultimately replace most open repairs of abdominal and thoracic aneurysms. However, this replacement evolution is still ongoing and in some cases is still controversial. Thus, currently there is still a need for open surgical repair in some patients with aortic aneurysm disease.

Chapter 54

Surgical Treatment of Vascular Occlusive Disease

Amanda Feigel and Alan Dardik

Peripheral arterial disease (PAD) describes the spectrum of disease, from asymptomatic to severe, of diminished or absent arterial blood flow to the lower extremities or abdominal viscera. PAD is usually distinguished from extracranial and intracranial carotid disease, as well as coronary disease, although all of these entities are usually and most commonly caused by atherosclerosis. Symptoms of PAD can be present either acutely, caused by plaque rupture releasing distal emboli, or chronically, caused by the progressive intimal thickening leading to decreased luminal diameter and subsequent reduced

distal blood flow. As atherosclerotic intimal thickening is typically indolent, slowly accumulating plaque reducing blood flow over many years, the elderly population is commonly affected with PAD. This chapter focuses on the impact of PAD in the lower extremity and visceral circulations in elderly patients. Recent advances in minimally invasive technologies, particularly endovascular treatments, have increased options for treatment of PAD in the elderly patient. However, the evidence for the efficacy of these newer technologies is rarely established in the elderly population.

CASE STUDY

An 85-year-old man presents for a second opinion regarding a right great toe ulcer that was ischemic, but not infected. He had a history of claudication treated with exercise approximately 10 years prior to presentation. He also had a history of coronary artery disease treated by coronary artery bypass approximately 8 years ago. There is a history of hypertension and type II diabetes but no recent smoking. He takes aspirin and a statin.

The physical exam is remarkable for his vascular exam. Femoral pulses are 2+ bilaterally, but there are no palpable popliteal, dorsalis pedis, or posterior pulses bilaterally. The ankle-brachial index is 0.3 on the right and 0.5 on the left. The right great toe has an ulcer that is clearly ischemic, painful to the point that motion is

reduced; there is no cellulitis or exudate. There is no gangrene. The contralateral foot has trophic changes but is not frankly ischemic.

The patient claims to be able to perform his basic activities of daily living, but exam shows that he is probably chronically malnourished and mildly dehydrated, although there are no signs of dementia. He lives alone, having been recently widowed. The patient has already had an opinion from a general surgeon recommending primary amputation for his severe vascular disease; your office confirms these records and notes that the surgeon's opinion was based both on the patient's age as well as a computed tomogram (CT) angiogram. The patient is particularly concerned as he believes that an amputation will prevent him from returning home, forcing him to move permanently to a nursing home.

Incidence and Epidemiology

The incidence of PAD is typically noted to range from 3 to 10% in the general population, but the incidence increases to 15–20% in patients older than 70 years [1]. The prevalence of PAD increases dramatically with age (Fig. 54.1). For

FIGURE 54.1 Increasing prevalence of PAD with age.

example, the PARTNERS study found that PAD was present in 29% of patients either ≥ 70 or 50–69 with a risk factor for PAD [2]. Additional risk factors independent of age include non-White ethnicity, male gender, smoking history, diabetes, hypertension, and dyslipidemia.

The increased incidence and prevalence of PAD in the elderly is especially significant since presence of PAD, even if only asymptomatic, increases the risk of coronary and cerebral arterial disease [2]. Patients with either claudication or critical limb ischemia have reduced long-term survival compared to age-matched control patients; for example, 10-year survival is reduced from 90 to 50% in patients with claudication and to 10% in patients with critical limb ischemia [1].

Patient Assessment

The initial evaluation of elderly patients with arterial occlusive disease is critical. Atherosclerotic disease of the aortoiliac segment is often asymptomatic in many elderly patients secondary to their sedentary life style. Few elderly patients present with lower extremity or buttock claudication secondary to either isolated infrainguinal or aortoiliac disease. Instead, they more commonly present with limb-threatening lower extremity ischemia (rest pain, ischemic ulceration, gangrene) secondary to multilevel arterial occlusive disease. The combined burden of aortoiliac and infrainguinal arterial occlusive disease can be more difficult to assess and treat in this patient population. After a complete physical examination that includes a careful pulse examination, noninvasive studies are helpful for evaluating the patient's arterial disease. The vascular laboratory may aid in the evaluation and selection of patients for single or multilevel revascularization. If an intervention is indicated, further invasive studies may be performed to define the best intervention for the individual patient, although recent technological advances may limit the need for invasive purely diagnostic studies.

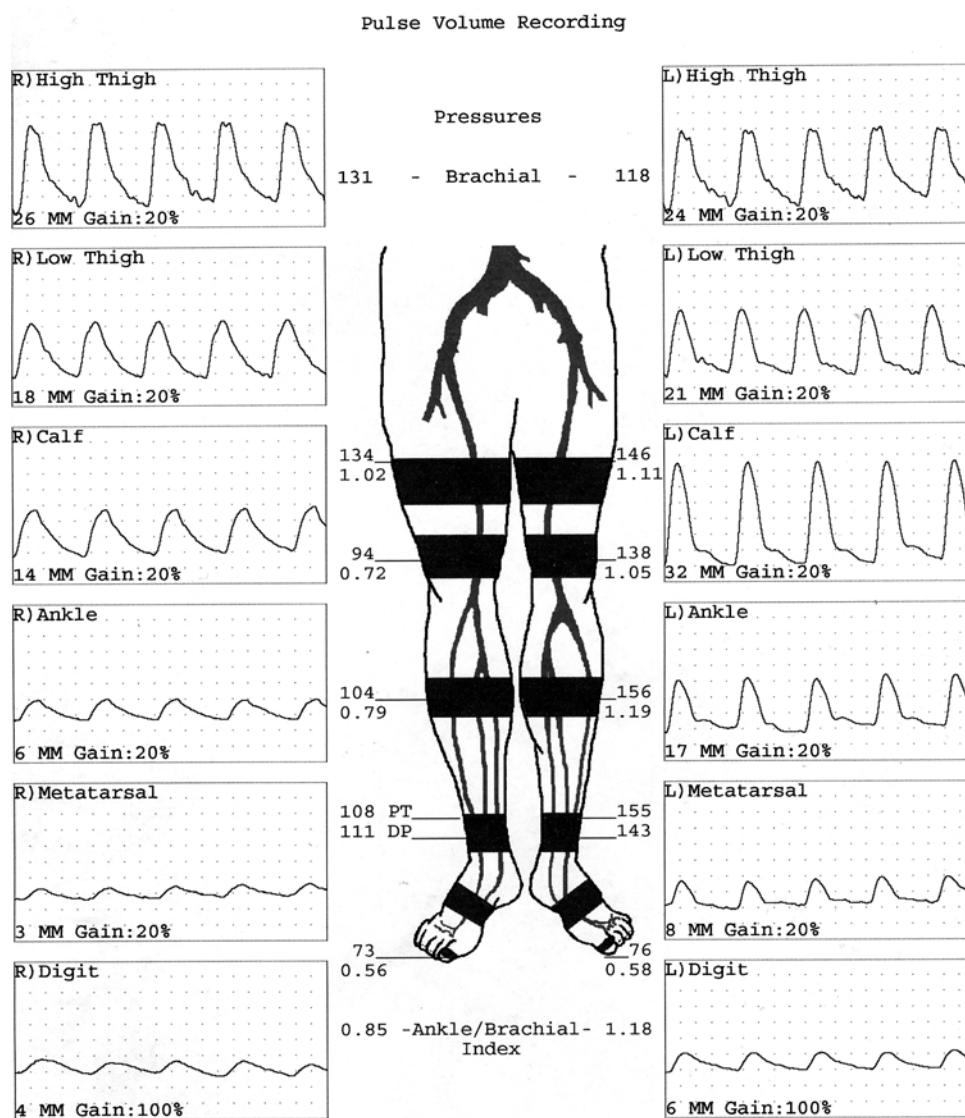

The ankle-brachial index (ABI) is determined by dividing the ankle pressure in each lower limb by the higher of the two brachial pressures. Patients with normal circulation have an ABI in the range of 1.0–1.2, those with claudication have reduced ABIs in the range of 0.40–0.90, and those with limb-threatening ischemia have ABIs in the range of 0–0.5. An important limitation of measuring lower extremity pressure occurs in patients with heavily calcified vessels, mostly diabetics and patients with end-stage renal disease. In these patients, the ABI is falsely elevated owing to the higher pressure required to occlude calcified vessels, and in some cases, the vessels are not occluded even with pressures higher than 300 mmHg. However, all-cause mortality is increased both in patients with reduced ABI as well as in patients with elevated and incompressible ABI [3].

Pulse volume recordings (PVR) are obtained using a calibrated air plethysmograph. A PVR waveform is generated for different levels of the lower extremity using standard blood pressure cuffs. The increase in pressure within the cuff resulting from the volume increase during systole is recorded as a pulse wave. The tracings are characterized as normal when there is a brisk rise during systole and a dicrotic notch, as moderately abnormal when there is loss of the notch and a more prolonged downslope, and as severely abnormal when there is a flattened wave. The absolute amplitudes are not comparable from patient to patient, but serial PVRs have been shown to be highly reproducible, making them useful for following the course of patients with severe peripheral vascular disease. In addition, this test cannot easily differentiate proximal femoral disease from iliac occlusive disease. Figure 54.2 shows a typical PVR tracing demonstrating both thigh (superficial femoral artery) and tibial disease on the right.

Duplex scanning can be a useful noninvasive technique for assessing the aortoiliac and infrainguinal arterial system. A variety of studies have evaluated the ability of this technique to predict iliac artery stenoses. Kohler et al. initially suggested that duplex scanning had excellent sensitivity (89%) and specificity (90%) when used to predict an iliac stenosis of 50% or more [4]. Three subsequent studies by Langsfeld et al. [5], Moneta et al. [6], and Legemate et al. [7] corroborated these findings with sensitivities ranging from 81 to 89% and specificities ranging from 88 to 99%. These noninvasive evaluations may be useful for evaluating the elderly prior to invasive procedures such as angiography and angioplasty.

Until recently, computed tomography angiography (CTA) has had limited use in the evaluation of aortoiliac occlusive disease other than simple identification of severely calcified arteries or lesions. However, faster, new generation spiral CT scanners have the capability of three-dimensional reconstructions and provide significantly improved images (Fig. 54.3). The outstanding resolution of the newer generation of these studies has led to their routine use to evaluate patients with PAD in many centers. A distinct advantage of these new CTA

FIGURE 54.2 Typical PVR tracing demonstrating both thigh (superficial femoral artery) and tibial disease on the right.

is the ability to simultaneously identify coronary artery disease, and thus perform risk stratification [8]. However, approximately 150 cc of intravenous contrast dye is required for most CTA, limiting the use to patients with essentially normal renal function. As the newer generations of CT scanners become faster, they have increased ability to accurately image elderly patients who, due to comorbidities such as congestive heart failure, may have limited tolerance to lie still for the duration of the study. As such, CTA is becoming more popular as a diagnostic tool in elderly patients.

Magnetic resonance angiography (MRA) is noninvasive, does not require contrast agents, and allows good arterial imaging. Owens et al. [9] and Carpenter et al. [10] showed that MRA may be more sensitive than arteriography when imaging distal lower extremity runoff vessels. Carpenter et al. [11] also reported that MRA had a 100% positive predicted value (PPV) and a 98.6% negative predicted value (NPV)

when compared to contrast angiography for evaluating patients with aortoiliac occlusive disease. These findings have not been widely reproduced, but this noninvasive modality has the potential to replace contrast arteriography in the evaluation of these patients. Current images are generally inadequate for therapeutic planning in most centers, but as the associated hardware and software improve, and interest by dedicated MR radiologists increases, the role of MRA in the assessment of occlusive disease of the aortoiliac segments will increase [12].

Intraarterial contrast angiography is considered the gold standard for evaluating patients with arterial occlusive disease. This modality provides the diagnostic information necessary to plan the treatment of most vascular patients with arterial occlusive disease. Complete evaluation of the existing arterial disease from the aorta to the pedal vessels is typically necessary for elderly patients as they commonly have

FIGURE 54.3 Utility of CTA in diagnosis of PAD. CTA shows occlusion of left common femoral artery and superficial artery. (a) Two-dimensional coronal reconstruction. (b) Three-dimensional reconstruction.

multilevel occlusive disease. The addition of intraarterial pressure measurements at the time of arteriography improves the accuracy of detecting clinically significant stenosis. Pressure measurements after intraarterial injection of a vasodilatory drug such as papaverine are used to evaluate the significance of aortoiliac stenoses under conditions of stress that require increased blood flow through these vessels. A systolic pressure gradient across the lesion of more than 15 mmHg is considered hemodynamically significant.

The complication rate of arteriography in the general population is only 1.7–3.3% [13]. Elderly patients with severe aortoiliac or infrainguinal disease must be carefully evaluated before the procedure, as local and systemic complications are more likely than in the general population. The transfemoral approach is the safest, but other options (e.g., translumbar, transbrachial, or transaxillary approach) may have to be used for patients with weak or nonpalpable femoral pulses. These alternative approaches have higher local complication rates. Complications include hematomas, pseudoaneurysms, dissections, thrombosis, and embolization.

Renal insufficiency is an important complication of angiography. Renal impairment associated with contrast agents occurs in 6.5–8.2% of patients who undergo arteriography [14, 15]. Patients with preexisting azotemia and a baseline serum creatinine level >2.0 mg/dl are at the highest risk of renal complications after angiography. Elderly patients have a low creatinine clearance rate for a given serum creatinine level, so they should always be considered at high risk for nephrotoxicity. All possible precautions must be taken to limit the renal insult. The use of low osmolar contrast agents has been shown by some to decrease the incidence of renal impairment [16, 17], but these findings are not universal [18]. Adequate hydration prior to arteriography is an effective maneuver to diminish the risk of contrast nephropathy. Mannitol is used for its osmotic diuretic effect to help prevent contrast toxicity. Vasodilators such as dopamine have also been used because the nephrotoxic effect of contrast agents is considered to be partly due to intrarenal vasoconstriction. Dopamine has been shown to be better than mannitol for preventing contrast-related renal insufficiency [19]. Unfortunately, many elderly patients have

moderate to severe cardiac disease, and aggressive hydration may lead to congestive heart failure, cardiac ischemia, and arrhythmias. In addition, the use of dopamine may lead to cardiac complications. Careful hydration and judicious use of mannitol, dopamine, and contrast agents can decrease the incidence of renal impairment associated with arteriography.

Therapeutic Management

Medical management of PAD focuses on lifestyle modification to reduce risk factors for progression of atherosclerotic disease. These include smoking cessation, addition of a lipid lowering agent such as a statin, antiplatelet therapy, and increased daily exercise, as well as supervised exercise classes. Conservative management is invariant for all patients regardless of age. When it has become evident that medical therapy has failed, surgical and/or interventional approaches become the mainstay of treatment.

Elderly patients with mainly aortoiliac occlusive disease rarely require an intervention. Patients with claudication should be treated initially by maximizing the management of the known risk factors for the development of atherosclerosis, an exercise or walking program, and the use of potentially helpful oral agents such as pentoxifylline. The small group of patients with severe, debilitating claudication that has failed the initial treatment protocol generally request an intervention. In addition, patients who present with limb-threatening ischemia secondary to multilevel occlusive disease should be considered for intervention.

Acute Thromboembolic Disease

Severe forms of acute ischemia typically result from embolic occlusion of a previously patent vessel. Sources of embolism are typically of a cardiac nature but can also originate from aneurysms and proximal arteries. Occlusion of a vessel from progressive growth of a thrombus is more gradual and allows for development of collateral vessels. Therefore, chronic occlusive disease typically results in less severe ischemia and pain compared to acute disease.

Acute arterial ischemia presents similarly in elderly and younger patients with early neurological signs including pain, weakness, pallor, paresthesias, and lastly pulselessness in affected extremities (Table 54.1). Pain is the most common complaint, and numbness of the web space between the first and second toes is the earliest neurologic sign of ischemia. Extremities are relatively resilient to ischemic conditions for up to 5–6 h, after which irreversible damage may

TABLE 54.1 Signs of acute arterial ischemia

Pain
Paralysis
Pallor
Paresthesia
Pulselessness
Poikilothermia

occur. However, elderly patients may be reticent to complain and as such may present at a later stage of disease.

Systemic anticoagulation with intravenous heparin will prevent propagation of either the embolus or thrombus distal to the site of occlusion resulting from stagnant flow. A traditional angiogram or a CT angiogram can be performed to determine the area of occlusion. Once the location is known, early revascularization is often indicated to salvage the extremity. This can be accomplished by either surgical intervention and placement of a bypass graft, such as femoral-popliteal bypass, or through endovascular techniques for patients who may not be operative candidates or otherwise have amenable anatomy.

Chronic Occlusive Disease

Claudication rarely indicates a risk for limb loss and typically responds to lifestyle modifications. Conversely, rest pain represents critical ischemic disease in which blood flow is insufficient even for basal metabolism. Rest pain occurs in the dorsum of the foot and is increased in intensity when the limb is elevated and resolves with dangling the affected limb, allowing gravitational forces to assist perfusion. Additional signs of markedly decreased blood flow include loss of hair, thinning skin, and muscle wasting. Rest pain represents the presence of critical ischemia, similar to gangrene and non-healing ulcers; thus, the patient with rest pain should be evaluated for revascularization expeditiously.

PAD: Surgical Intervention

Femoral-popliteal bypass is usually performed for limb-threatening ischemia or severe, lifestyle-limiting claudication. Numerous reports have documented that elderly patients more frequently require surgery for limb-threatening ischemia, with operative urgency, than for claudication alone. Autologous saphenous vein remains the conduit of choice, with polytetrafluoroethylene (PTFE), dacron, and human umbilical vein being the most common prosthetics used when autologous vein is not available.

TABLE 54.2 Outcome of femoral-popliteal bypass grafts in elderly patients

Trial (Reference)	Year	Level of evidence	Randomized patients (<i>n</i>)	Intervention/design	Median follow-up	Minor end point	Major end point	Age	Interpretations/comments
[20]	2000	1b	240	Randomized multicenter	21 Months	Graft thrombosis	Death	≥65	5-year patency 55%
[21]	2001	2b	349	Retrospective cohort series	3 Years	Limb salvage	Graft patency	>70	5-year patency 82%
[22]	1986	4	168	Case series	–	Graft thrombosis	Death	≥80	3-year patency 62%
[23]	1987	4	46	Case series	41 Months	Graft thrombosis	Death	≥80	83-year patency 78%
[24]	1989	4	50	Case series	–	Graft thrombosis, limb salvage	Death	≥80	3-year limb salvage 80%

Outcomes of femoral-popliteal bypass graft placement in elderly patients are reviewed in Table 54.2. Two studies provide good evidence that elderly patients undergo femoral-popliteal bypass with patency at least equivalent to, and possibly even better than, that achievable in younger patients. In a multicenter, randomized trial comparing prosthetic grafts used in above-knee bypass, Green et al. reported that the type of prosthetic graft has little effect on outcome, but patients over 65 years old had significantly greater 5-year graft patency compared with younger patients (55% vs. 36%) [20]. Similarly, Lau et al. reported improved 5-year vein graft patency in patients over 70 years of age compared with patients less than 70 years of age (82% vs. 72%) [21]. All studies reported excellent limb salvage in elderly patients [20–24].

Outcome after more distal infrageniculate bypass surgery is similarly favorable in the elderly. Hearn et al. reported in a retrospective cohort series that patients ≥70 years of age had 5-year primary and secondary graft patency rates of 61 and 74%, respectively, which was similar to patients under the age of 70 years who had rates of 76 and 79%, respectively [25]. Similarly, excellent results of case series have been reported [26, 27].

We believe that if an elderly patient faced with a need for limb salvage can tolerate the perioperative mortality and morbidity risk of the cardiovascular stress of the procedure, the limited evidence available favors an aggressive approach to bypass surgery. However, the minimally invasive nature of endovascular procedures and their overall efficacy in short-term reports have led many authors to advocate for this therapy primarily in elderly patients.

Endovascular

The use of percutaneous transluminal balloon angioplasty (PTA) for the treatment of aortoiliac occlusive disease and superficial femoral arterial disease, with or without the use of intravascular stents, has flourished over the past decade. Multiple series in the literature have described a variety of factors that can affect the long-term results of iliac angioplasty

TABLE 54.3 Predictors of success after balloon angioplasty

Larger artery
Shorter lesion
Less severe clinical indication (claudication vs. critical limb ischemia)
Less severe degree of stenosis (stenosis vs. occlusion)
Excellent runoff distal to lesion (excellent vs. compromised)

and are now known to be applicable to balloon angioplasty in general (Table 54.3). Predictors of a long-term successful outcome after balloon angioplasty include the location of the lesion (common iliac lesions respond better than external iliac artery lesions), indication for therapy (patients with claudication respond better than those with limb-threatening ischemia), severity of the lesion (arterial stenoses respond better than arterial occlusions), and arterial runoff distal to the lesion (lesions with good runoff respond better than those with poor runoff).

A recent Italian study has reported the results of 37 elderly patients aged 80–89 with critical limb ischemia at high risk for surgery; 102 lesions were treated with PTA [28]. The overall technical success was 84%; however, 85% of patients had reocclusion within 1 year. Despite this high rate of restenosis and reocclusion, complete or partial wound healing was achieved in 80%, and rest pain was improved in 57% of patients, achieving a total limb salvage rate of 74% [28]. The authors suggest that even temporary vascular patency after PTA enables adequate wound healing in elderly patients, recommending a primary endovascular approach. Similar results were found in an Israeli study [29]. Most recent series similarly report excellent limb salvage despite low primary patency as assisted primary and secondary patency rates are excellent [30].

Early reports on the results of angioplasty supported the use of stents after angioplasty failures, dissections, or more complex lesions to improve the results of iliac artery interventions. The role of stenting after angioplasty remains controversial, with some authors recommending primary stenting and others advocating a more selective approach. We have found that high-risk patients, including elderly

patients, have excellent results after stent placement in the superficial femoral artery [31].

Numerous additional variations on the basic angioplasty theme are currently being evaluated in patients with PAD, including elderly patients. Some of these options include: (1) subintimal angioplasty, in which the wire is intentionally placed in a dissection plane in the arterial media, to assist crossing of otherwise difficult lesions; (2) remote endarterectomy/plaque excision, in which the plaque is shaved off layers at a time; (3) laser atherectomy, in which a laser is used to destroy the plaque; (4) orbital atherectomy, in which a diamond-coated crown rotates to “sand away” plaque; (5) cryoplasty, the use of liquid nitrogen to inflate the angioplasty balloon, simultaneously freezing the plaque; (6) cutting balloon, in which fine microtomes are placed on the balloon to limit dissection and promote expansion of calcified plaques; (7) resorbable stents, in which a stent is placed that is absorbable with time; (8) covered stents, in which a totally endovascular endoluminal “bypass” can be performed; and (9) drug-eluting stents, in which pharmacological agents that prevent restenosis are delivered from the stent. None of these adjunctive therapies has been convincingly found to have long-term benefits at this time, in any group of patients, let alone elderly patients. It is likely that additional technologies will be developed and evaluated in the future, and the continued proliferation of these advances, coupled with the desire to treat patients with the latest advances, will continue to prevent timely randomized prospective studies of these endovascular technologies.

The Columbia group recently has reported its results of plaque excision using the Silverhawk atherectomy device [32]. 579 lesions in 275 patients, with a mean age of 70 years, were treated; 37% were claudicants, and 63% had critical limb ischemia. The authors reported 18-month primary patency of 53%, and secondary patency of 75%; limb salvage was 92% [32]. These excellent results require confirmation from additional groups, as results in younger cohort groups are not so optimistic.

Similarly, the Below-the-Knee Chill Study reported its initial experience with Cryoplasty (cold balloon angioplasty). 108 patients with a mean age of 73 years, presenting with critical limb ischemia, were treated and followed for 6 months; there were six major amputations (6.6%) and five deaths; amputation-free survival was 89% [33]. However, in a group of 64 patients with a mean age of 81 years, Samson reported only 38% freedom from restenosis at 24 months and an extra \$1,700 cost per procedure for cryoplasty, suggesting that this therapeutic modality is not cost-effective [34].

We believe that a balanced approach is needed when infrapopliteal angioplasty is required. Restenosis, reintervention, and amputation are high after tibial angioplasty performed for critical limb ischemia, although an attempt at PTA is often indicated; excellent limb salvage rates may be

obtained with careful follow-up and reintervention when necessary, including surgical bypass [35].

Stem Cell Therapy

The use of autologous stem cells for patients with unreconstructable ischemia is being explored. Initial results have described both bone marrow-derived as well as circulating peripheral blood-derived stem cell isolation; these stem cells are then reinjected into the ischemic leg to promote angiogenesis and arteriogenesis, resulting in relief of rest pain, healing of ulcers, and limb salvage [36, 37]. However, randomized trials have yet to confirm these exciting reports, preventing widespread usage of this technology to date. The use of stem cell therapy in elderly patients is not intuitive, as elderly patients may have reduced stem cell numbers, function, quality, and ability to isolate these cells from the marrow or circulation, compared to younger patients. Nonetheless, stem cell therapy may be an exciting alternative therapy for patients without other options, and its minimally invasive nature is especially appealing to elderly patients.

Chronic Visceral Ischemia

Progressive atherosclerotic stenosis and occlusion of the visceral arteries is often asymptomatic but ultimately can result in end organ damage to either the kidneys or the bowel. Renal artery stenosis is a relatively less common location for atherosclerotic lesions compared to the usual peripheral and cardiac locations; a renal artery stenosis greater than 60% may stimulate the kidney to release renin into the bloodstream, resulting in brittle hypertension. This affects 6.8% of patients older than 65 years [38]. Renovascular hypertension, however, is associated with increased risk of adverse coronary events in these patients [38]. If medical management fails, traditional surgical revascularization has excellent results; Benjamin et al. reported that age ≥ 60 was not a risk factor for mortality after renal artery bypass [39]. However, percutaneous angioplasty with placement of endoluminal stents is currently the most common procedure performed. Success rates of 65–80% and restenosis rates of 11–17% have been reported for the general population [40–42]. A French group found renal artery angioplasty to reduce by 60% the number of patients requiring two or more medications for blood pressure control [43]. However, this study excluded patients over the age of 75, and its findings have not been verified in the elderly population. The Wake Forest group reported its results of

110 renal artery angioplasty/stent placements in 99 patients, with a mean age of 69 years; the glomerular filtration rate was improved in only 28%, and the number of antihypertensive agents decreased modestly (3.3 ± 1.2 versus 3.1 ± 1.3 postintervention, $P=0.009$) [42].

Asymptomatic celiac trunk or mesenteric artery stenosis is common, present in 17.5% of the population over 70 years of age, but was not associated with increased mortality [44]. Chronic mesenteric ischemia, resulting in intestinal angina, is thought to be associated with progression of disease beyond a single vessel and/or loss of collaterals. Acute occlusion of blood flow to the bowel by an embolic source can be a catastrophic event to the elderly patient and is associated with high mortality. Nonocclusive acute occlusion typically occurs in the critically ill and elderly who have low cardiac output states combined with diffuse mesenteric vasoconstriction.

Options for surgical correction of mesenteric stenoses or emboli include percutaneous angioplasty, stent placement, endarterectomy, and bypass procedures, all with limited success. Mesenteric artery endarterectomy and bypass is generally reported to be a safe and durable surgical procedure in patients with good surgical risk; operative mortality is typically <5% in elective cases. However, increased mortality is associated with age as well as renal insufficiency, suggesting a role for minimally invasive therapy in elderly patients [45].

Brown et al. [46] retrospectively analyzed 14 patients with a mean age of 73 years, having undergone mesenteric angioplasty and stent placement. This group reported a high

early restenosis rate resulting in 53% of patients requiring reintervention within the 13-month follow-up period. However, 93% of patients remained symptom-free at the conclusion of the study [46]. Similarly, high symptom-free rates have been reported with mesenteric artery reconstruction, 80% at 5 years and 60% at 10 years [47]. Given these excellent functional results, mesenteric artery angioplasty with stent placement can be reasonably recommended for patients with limited life expectancy; however, surgical artery reconstruction remains the treatment of choice for patients with average life expectancy.

Summary

Vascular surgery is stressful in all patients and certainly in the elderly. Larger operations such as aortobifemoral bypass have increased perioperative morbidity and mortality that all patients with extensive comorbidities, such as many elderly patients, have difficulty tolerating with ease. For these physiologically elderly patients, minimally invasive approaches such as PTA, without or with stent placement, may be beneficial; long-term results may or may not be beneficial in this group of patients with limited life expectancy. On the other hand, the technically proficient conduct of most high-risk vascular surgical procedures, with aggressive pre-, intra-, and postoperative medical optimization, allows safe application to elderly patients [48]. Operations that are more limited in

CASE STUDY

An angiogram that you perform shows mild disease in the superficial femoral artery as well as severe proximal tibial disease; the dominant runoff vessel to the foot is the anterior tibial artery (Fig. 54.4). The patient's cardiologist believes that he is at moderate risk for procedures, but if beta-blockers are given perioperatively, no additional preoperative testing needs to be performed.

The patient is taken to the operating room where the superficial artery disease (Fig. 54.5a) is treated with both cryoplasty (Fig. 54.5b, c) as well as a 5 mm × 30 mm stent (Fig. 54.5d, e). The outflow disease is treated by an SFA-anterior tibial bypass using the ipsilateral vein.

After a 1-week postoperative recovery, the patient was able to be discharged to home, with a visiting nurse to monitor the healing toe. Follow-up at 3 months showed that the toe ulcer healed completely, and the patient was able to resume independent living.

scope, producing less physiological disturbance, are usually well tolerated by elderly patients. For example, carotid endarterectomy provides stroke-free survival benefit, and peripheral bypass surgery provides limb salvage; these procedures should not be denied to patients on the basis of age alone.

Chapter 55

Natural History and Treatment of Extracranial Cerebrovascular Disease in the Elderly

George H. Meier and Carlos Rosales

Cerebrovascular disease, specifically stroke, continues to increase despite improvements in the treatment and outcomes of cardiovascular disease in general. Many believe that the development of cerebrovascular atherosclerosis is simply a normal consequence of aging, as the incidence of stroke increases with age, rising almost sevenfold between the ages of 55 and 85 [1]. Despite a better understanding and advances in medical management, cerebrovascular disease remains the third leading cause of death in the United States [2]. It is therefore not surprising that carotid endarterectomy remains one of the most common peripheral vascular operations done in the United States [3]. Current estimates suggest that the population over the age of 65 will more than double by the year 2050 [4], by which time the likely increase in cerebrovascular disease will result in a marked impact on medical care. The correct and cost-effective management of cerebrovascular disease is therefore increasingly important as the population ages.

Cerebral infarction can be caused by intracerebral hemorrhage or embolic disorders. Although hemodynamic flow limitations can occur, flow-related cerebral ischemia is rare. Previous studies have suggested that about 60% of cerebrovascular events originate with atherosclerotic disease outside the heart [5]. Thus, most embolic strokes should be preventable if the extracranial vascular disease can be diagnosed and treated prior to an irreversible cerebrovascular event. This intervention may be as simple as limiting plaque growth with medical management once carotid disease is discovered, or it may require complex reopening of the arterial supply with surgical or endovascular techniques. Stroke prevention requires not only modification of risk factors for atherosclerosis but also appropriate selection of patients for intervention prior to the occurrence of a limiting cerebrovascular event.

Risk factor modification in those with atherosclerosis is an area of intense, ongoing investigation and review.

Traditional risk factors for atherosclerotic disease such as smoking [6], hypertension [7], and diabetes [8] remain significant for patients with extracranial atherosclerosis. Research suggests that other risk factors such as elevated homocysteine [9] and low-density lipoprotein (LDL) cholesterol [10–12] may be important in lowering the ultimate risk of stroke. Elevated homocysteine levels in the bloodstream have been implicated in numerous atherosclerotic disease processes [13, 14]. Whereas homozygous individuals with a deficiency of enzymes to metabolize homocysteine often die at a young age secondary to coronary disease [15], heterozygous individuals maintain function but appear to have an increased tendency to develop atherosclerosis. The management of these elevations is relatively simple, as three inducible enzyme systems allow breakdown of homocysteine into safer metabolites. These inducible systems increase their activity in response to folate, vitamin B₆, and vitamin B₁₂, respectively. While it remains simple to replace these vitamins, multiple studies have shown no benefit in cardiovascular disease prevention [16, 17].

The cholesterol saga has been a fundamental issue with respect to coronary disease for years. Cholesterol has traditionally been linked to coronary atherosclerosis [18] but has also been implicated strongly in cerebrovascular disease [19]. Whereas atherosclerotic plaque initiation is little influenced by cholesterol levels, progression of plaque already in place is clearly accelerated by elevated cholesterol levels. Evidence suggests that the reduction of cholesterol using 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, even in individuals with normal levels, may lower the risk of subsequent cardiac events [20]. The CARE trial demonstrated a 31% reduced incidence of stroke with the use of pravastatin in patients with previous myocardial infarction [21]. The largest trial thus far is the Heart Protection Study, which showed a significant reduction in stroke/TIA on patients taking simvastatin versus placebo. When evaluating all cardiovascular end points, a relative risk reduction of 23.6% was achieved [22]. The SPARCL trial took patients with recent stroke or TIA and randomized them to atorvastatin or placebo. The stroke rate for the

Cincinnati, OH, USA
e-mail: george.meier@uc.edu

placebo group was 13.1% versus 11.2% for the treatment group (RRR 2.2%). The absolute risk reduction for major cardiovascular events was 3.5%. When examining the subset of patients with carotid stenosis in the SPARCL trial, atorvastatin was associated with a 33% reduction in the risk of any stroke, and the need for carotid revascularization was reduced by 56% [23, 24]. These and multiple other studies have proven that statins are clearly beneficial in stroke prevention and should be used in all patients with carotid disease.

Antiplatelet therapy is another very important tool when managing cerebrovascular disease. Multiple trials have shown the benefit of aspirin in stroke prevention. The International Stroke Trial showed a reduction of reinfarction rate within 2 weeks of an ischemic stroke in patients treated with aspirin [25]. In the CAST study, those patients treated with aspirin had a 12% RRR for stroke and death in the 4 weeks following acute stroke [26]. Several recent studies have evaluated the role of clopidogrel in stroke prevention. The Clopidogrel Versus Aspirin in Patients at Risk of Ischemic Events Trial (CAPRIE) concluded that clopidogrel was slightly superior to aspirin in stroke prevention on patients with generalized atherosclerosis (8.7% RRR) [27–29]. This risk reduction is even higher (22.7%) in patients with disease in multiple vascular beds. The effects of aspirin alone versus aspirin and clopidogrel were evaluated in the CHARISMA trial [30, 31]. CHARISMA randomized patients with cardiovascular disease or multiple risk factors to either aspirin or aspirin and clopidogrel and looked at myocardial infarction, stroke, or death as the primary end point. The risk of future ischemic events in the aspirin group was 7.3% versus 6.8% for the dual therapy group. The relative risk reduction of 0.93 was not statistically significant. The RRR for symptomatic patients was statistically significant at 12% ($p=0.046$). Antiplatelet agents are proven of benefit to patients with proven stroke and should therefore be prescribed to all patients with carotid artery disease. Aspirin at either low or high dose is adequate for most patients, but clopidogrel should be considered in some situations, particularly in those patients with atherosclerotic disease in multiple vascular beds.

Early prospective randomized trials evaluating carotid treatments relied on a “Best Medical Management” arm for comparison to surgical treatment. While the standards of medical management at the time of these trials were quite different than today, best medical management today includes the use of statin therapy, antiplatelet agents, and other medical agents that were not available for routine use during previous trials. Clearly, physicians have become much better at slowing the progression of atherosclerotic disease with many new modalities not previously available. As a result, many observers question the comparisons previously used; current best medical therapy may be significantly better than that used for the trials and therefore raise questions as to whether or not the conclusions of the trials

remain valid in the current era. For this reason, historical controls are probably insufficient to determine outcomes for care. Newer trials have included new medical management arms whenever possible. Eventually, medical management should be effective at preventing progression of atherosclerotic disease; until that time, the medical management standard will be slowly drifting toward overall better outcomes.

Pathophysiology

Atherosclerotic disease begins early in life as plaque initiation starts in areas at risk for atherosclerotic degeneration [32, 33]. Most atherosclerosis is well explained by this mechanism, although some fundamental contradictions remain. If atherosclerosis is a progressive degenerative disease, it would be reasonably expected that its incidence would continue to increase with increasing age. Indeed, this appears to be true for cerebrovascular disease, but it is distinctly contrary to existing data relative to both coronary [34] and iliac [35] disease. In those distributions, a plateau occurs in the incidence of atherosclerosis, with decreasing incidence of disease once a certain age is reached. The explanation for this discrepancy is complex, and whether there is a real plateau in disease progression in these anatomic areas or whether a selection bias exists remains unclear. What data are available suggest that no such plateau exists for cerebrovascular disease, with the incidence of disease increasing with increasing age [35, 36]. Additionally, the increased incidence of cerebrovascular disease further explains the resultant increased incidence of stroke with increasing age [37].

The atherosclerotic plaque of cerebrovascular disease is no different from that associated with coronary or peripheral vascular disease. The initiating event appears to be the development of a lesion on the intimal surface of the artery, particularly in areas of low shear stress [38]. The carotid bifurcation has been studied extensively, as plaque formation in this distribution is more anatomically consistent than that seen in most other locations. Essentially, the bifurcation of the carotid artery generates an area of high velocity (and therefore high shear stress) at the septum between the external and internal carotid arteries and an area of low shear stress at the bulb of the internal carotid artery opposite the bifurcation. In fact, with the advent of color flow duplex ultrasonography, this area of flow separation and reversal can be easily defined in normal individuals. The flow phantom models of shear-related atherosclerosis have been best defined in this anatomic location. These models clearly demonstrate the areas of flow separation and resultant flow reversal opposite the bifurcation, where atherosclerosis is found consistently. Therefore, flow patterns at the carotid bifurcation appear to be important in

the initiation and progression of atherosclerotic plaque in the cerebrovascular system.

A second issue associated with atherosclerotic plaque progression is the concept of intraplaque hemorrhage (Fig. 55.1). With coronary artery disease, intraplaque hemorrhage is a well-accepted mechanism of sudden plaque progression associated with an acute myocardial event. Similarly, carotid atherosclerosis has been studied extensively relative to plaque morphology and intraplaque hemorrhage. The small blood vessels that traverse the complex intimal plaque of mature atherosclerosis are subject to significant hemodynamic effects, resulting in an increased risk of vessel rupture, with attendant intraplaque hemorrhage. Recently, new techniques in high-resolution ultrasound using intravenous ultrasound contrast have demonstrated this neovascularization of the plaque, suggesting that these images may predict which plaques are vulnerable [39–41]. The concept of plaque vulnerability becomes important when trying to predict which lesions are likely to progress and potentially cause symptoms. The association of intraplaque hemorrhage with increasing stenosis has been well documented [42]. Additionally, there has been a significant association of intraplaque hemorrhage with symptomatic carotid stenosis [43–46]. In this instance, the presence of subintimal hemorrhage results in intimal ulceration and embolization of residual intraplaque clot and debris, producing the characteristic microemboli associated with transient ischemic attacks (TIAs) [47]. Thus, intraplaque hemorrhage is associated with the severity of stenosis as well as the symptoms, suggesting that intraplaque hemorrhage may be the link between degree of stenosis and the incidence of symptoms. As a result, prediction of which plaques have an increased risk of intraplaque hemorrhage becomes important for both surveillance and asymptomatic intervention.

The origin of symptoms related to carotid atherosclerosis has not always been well defined. According to the hemodynamic theory, the symptoms associated with carotid stenosis were related to flow limitations and resultant cortical ischemia. In contrast, the embolic theory held that degeneration of the atherosclerotic plaque resulted in microemboli, and clot

FIGURE 55.1 Intraplaque hemorrhage associated with high-grade carotid stenosis.

formation caused macroemboli and stroke. The stumbling block for the embolic theory was the recurrent nature of similar symptoms with repeated episodes of transient ischemia. If a second TIA occurred, it was often with the same symptoms as seen during the previous attacks. How embolic debris could produce such repetitive symptoms was unclear. Two landmark studies served to resolve the conflict. First, the hemodynamics was evaluated by Kendall and Marshall [48]. In this study, patients with TIAs were subjected to pharmacologically induced hypotension. As the blood pressure was decreased, the patients were monitored for neurologic changes. None of these patients developed symptoms when their mean blood pressure was decreased significantly. Therefore, hemodynamic causes of transient ischemia seemed less likely [49].

The second study that ended the hemodynamic-embolic controversy was performed by Millikin at the Mayo Clinic [50]. In this study, baboons were anesthetized, and needles were inserted into the carotid flow. Small metallic beads were injected via these needles, and the brains were evaluated for the ultimate location of the beads. In a classic illustration from that study, the brain of one of the baboons was seen to have six beads lined up in the middle cerebral artery (Fig. 55.2). The insertion of the beads at a specific point in the flow resulted in emboli at a specific destination determined by the laminar flow patterns in the artery. In other words, the origin of the embolus determined its ultimate resting point. Thus, in one clear demonstration, the issue of recurrent symptoms resulting from multiple embolic events was resolved, confirming the embolic theory to be the best explanation for both TIAs and strokes [51, 52].

Given this evolution, the issue of hemodynamics has become a secondary issue in symptomatic cerebrovascular disease. Nonetheless, although certain patients clearly have flow compromise as an etiology for symptoms, their definition

FIGURE 55.2 Experimental demonstration of repetitive embolizations. In this baboon brain, embolization of metal spheres lodged in the same arterial segment with each sequential injection.

remains difficult. Anatomic studies have demonstrated that the circle of Willis, the traditional anatomic structure responsible for flow redistribution at the base of the brain, is incomplete in at least 25% of patients [53, 54]. With an incomplete circle of Willis, blood flow may be limited in its redistribution, resulting in areas of potential underperfusion. With additional atherosclerotic obstruction of the cerebral vessels, collateral flow may be compromised because of one of these congenital abnormalities in the circle of Willis. With a complete circle of Willis, normal anterior (carotid) circulation equates with normal posterior perfusion, even in the absence of native vertebral flow. In contrast, if one or both posterior communicating arteries are absent, vertebral or basilar artery disease may result in posterior circulation symptoms with completely normal anterior circulation. Given the frequency of abnormalities in the circle of Willis, maldistribution of flow is certainly possible in the setting of severe carotid or vertebral artery stenosis or occlusion.

Hemodynamic issues remain important when discussing watershed ischemia. Watershed ischemia occurs when perfusion to a segment of the brain is limited hemodynamically to a level below the blood flow necessary to maintain cell integrity. Infarctions then occur at the junction between two blood supplies, the so-called watershed zones. Watershed ischemia remains a topic of some controversy, but its occurrence remains ill-defined and sporadic. The classic scenario for watershed infarction due to underlying hemodynamic compromise occurs most commonly with open heart surgery using cardiopulmonary bypass. If a critical stenosis or occlusion is present, the diminished perfusion associated with the nonpulsatile, limited pressure flow of the heart–lung machine can produce watershed infarction in an area at risk. Carotid endarterectomy or carotid stenting prior to or simultaneous with coronary artery bypass surgery is done in an attempt to prevent these watershed infarctions [55–57].

The possibility of hemodynamic flow disturbance is reinforced by the occurrence of reperfusion syndromes after correction of severe carotid stenoses. In this scenario, the severe upstream stenosis results in the loss of autoregulation in the downstream cerebrovascular bed, with localized brain edema and risk of intracerebral hemorrhage resulting from reperfusion [58, 59]. Clearly, this loss of autoregulation represents a flow-limited response to a hemodynamically significant stenosis [60]. The difficulty is that flow-related ischemia is diffuse rather than focal, and evaluation of flow limitation is difficult with conventional intracranial imaging. Nonetheless, positron emission tomography has provided a window into overall brain blood flow and metabolism [61] and provides experimental insights into the frequency of flow limitation in the clinical setting. For the present, however, the basis for diagnosis and treatment of cerebrovascular disease focuses on the presence of a potential embolic focus, rather than on any potential for cerebrovascular flow limitation.

Diagnosis

Diagnostic testing in patients with cerebrovascular disease is essentially limited to two major areas: extracranial arterial imaging and intracranial arterial imaging. Each plays a fundamental role in the assessment of patients for carotid intervention. Because cerebral revascularization is focused on the extracranial carotid and vertebral arteries, arterial imaging is most important in these locations. Intracranial arterial imaging remains important, but its role continues to evolve as new modalities and technologies become available.

Anatomic definition in extracranial cerebrovascular disease is limited to two fundamental testing modalities: color duplex ultrasonography and arteriography. Each of these modalities has significant advantages and disadvantages, requiring more complete definition of their utility. Color duplex ultrasonography is a noninvasive technique for evaluating blood flow in any location accessible to an ultrasound beam (Fig. 55.3). The carotid and vertebral circulations were the initial focus of vascular ultrasonography development and remain the test bed for ongoing research in ultrasonographic diagnosis. Consistent visualization can be achieved in this location, resulting in reproducible diagnostic assessment of the severity and pattern of stenosis. Estimation of the degree of stenosis is based on several criteria, including peak systolic velocity, internal carotid/common carotid velocity ratios, and end-diastolic velocity. The most widely used criteria remain those of Strandness [62]. These criteria were developed to define percentage narrowing of the carotid bulb and have been verified in studies involving both angiographic and pathologic correlates [63]. Today, most carotid interventions are performed based on the data gathered from duplex ultrasound. It is also the standard to follow asymptomatic carotid stenosis with duplex ultrasound alone.

FIGURE 55.3 Duplex assessment of carotid using power Doppler.

The arteriographic assessment of cerebrovascular disease has remained essentially unchanged since the first cerebral angiogram by Moniz in 1927 [64]. Angiography results from injection of a radiopaque tracer intraluminally followed by exposure of an X-ray film or with use of a digital image intensifier. The choice of tracer today is usually a newer low osmolar nonionic contrast that has both lower incidence of allergic reactions and lower direct tissue toxicity. While traditional angiography involved X-ray film, currently, digital image processing techniques are used which not only lower radiation dose and contrast load but also provide archival images for digital storage (Fig. 55.4). While some institutions routinely use angiography for the diagnosis of cerebrovascular disease, many institutions have evolved to intervention based on ultrasound alone. As a result, angiographic diagnosis of cerebrovascular disease has faded, only to be somewhat revived by its use as a basis for carotid stenting. No specific combination of techniques dominates the arteriographic diagnosis of cerebrovascular disease, and institutional experience is more important than perceived advantages of one technique over another.

The diagnosis of atherosclerosis by arteriography requires documentation of intraluminal narrowing of the involved artery viewed in two planes. Because angiography is fundamentally a two-dimensional technique and atherosclerosis is three-dimensional, the assessment of luminal

FIGURE 55.4 Arteriographic image of left common carotid stenosis with ulceration.

narrowing requires perpendicular perspectives to state the degree of narrowing accurately. Measurement of internal carotid narrowing has traditionally been a calculation of the minimum residual lumen relative to an estimated arterial diameter in the carotid bulb. This estimation of the carotid bulb diameter is subject to interpretation and often results in overestimation of the degree of luminal narrowing. Fundamentally, the significance of any carotid stenosis resides in the degree of luminal encroachment relative to the outflow arterial diameter. This approach was first applied to the assessment of arteriographic diameter reduction in the NASCET trial [65] and subsequently was used for the Asymptomatic Carotid Atherosclerosis Study (ACAS) [66] as well. Currently, minimum residual lumen is compared to outflow arterial diameter for calculating the degree of stenosis. This technique is utilized both in ultrasound as well as an angiographic imaging. Angiography today is generally not necessary before surgery; it is most commonly used before a carotid stent or if the duplex ultrasound findings are unclear.

The earliest form of evaluation for intracranial pathology was the use of computed tomography without intravenous contrast [67]. While this new technology was revolutionary in its days, it was limited by the lack of vascular definition, ultimately necessitating IV contrast to define the limits of the vessels within the cerebral circulation. The addition of intravenous contrast to conventional CT imaging of the head and neck allowed not only the definition of intracranial parenchymal pathology but also the potential for vascular anatomic definition (Fig. 55.5). It only remained for high-resolution scanning techniques to be developed to allow angiographic equivalence using spiral CT technology.

Currently, CT angiography is used as a preliminary step in imaging in many patients with symptomatic carotid disease; evaluation for intracranial pathology can be coupled with surface mapping of the arteries to define three-dimensional anatomy for both the intracranial and extracranial vessels. What are the limitations of CT angiography? Primarily, the limitations center on differentiating the presence of intravenous contrast from that of the calcific vessel [68–70]. Calcium appears as a bright tissue on CT imaging and when it is confluent with the IV contrast, the interface between the two cannot be easily differentiated. As a result, calcified atherosclerosis, a common component of advanced extracranial carotid plaque, can be a confounding factor that limits the interpretation of luminal stenosis relative to the plaque associated with the stenosis. Nonetheless, as a screening tool, computed tomographic angiography is a useful adjunct prior to planning procedures, particularly when contrast angiography will be employed at the time of treatment such as with carotid stenting. In the setting, intracranial pathology is ruled out, and an estimate of anatomic disease is achieved. When coupled with duplex ultrasonography of

FIGURE 55.5 Surface mapping of CTA image showing normal carotid anatomy.

the carotid bifurcation, a highly accurate assessment of the degree of vascular disease in the extracranial carotid circulation can be achieved.

The most promising technology for intracranial and vascular imaging has been magnetic resonance imaging. With advances in magnetic resonance techniques, the possibility of a noninvasive technique for arterial imaging becomes more likely [71]. The difficulty with magnetic resonance angiography (MRA) lies in differentiating stenosis from occlusion. Any significant stenosis results in downstream turbulence. As a result, turbulence mixes once-aligned magnetic dipoles, resulting in signal dropout. Similarly, an absence of magnetic dipoles as is seen with arterial occlusion can also lead to signal dropout. Therefore, conventional time-of-flight MRA techniques overestimate arterial stenoses (Fig. 55.6), making diagnosis of stenosis versus occlusion reliant on other imaging techniques. Many studies have evaluated this issue. In high-grade stenosis, the correlation with ultrasound is high. Unfortunately, it is in the patient with moderate degrees of stenosis where the correlations fall off: MRA often overcalls the degree of stenosis in moderate or lesser levels of carotid disease [72]. Nonetheless, the combination of arterial imaging with intracranial parenchymal imaging makes MRA attractive in symptomatic patients. If intervention is contemplated, however, carotid evaluation with duplex ultrasonography or angiography is necessary.

FIGURE 55.6 Magnetic resonance angiogram demonstrating signal dropout associated with stenosis.

Treatment

Management of the Symptomatic Patient

Over the past few years, management of symptomatic carotid disease has progressed from an algorithm based on anecdotal reports to one based on significant scientific data owing primarily to publication of the NASCET study [73]. The prognosis of surgical versus medical management is clearly defined for the symptomatic population. More recently carotid stenting has been used in the symptomatic patient and is currently approved for “high-risk” patients with symptomatic disease. Despite the data that exist, numerous questions arise specific to an elderly population.

The NASCET trial for patients with symptomatic carotid disease enrolled only patients less than 80 years of age for a randomized study of surgery versus medical therapy.

Therefore, although the conclusions remain important, the results of necessity must be extrapolated to the elderly population over 79 years of age. The NASCET trial was terminated early in the high-grade stenosis group because of the significant benefit of surgery relative to medical therapy in patients with more than 70% stenosis by NASCET criteria. These results have been extended to the patient population with 49–70% stenosis demonstrating similar (though more limited) benefits to surgical management [74]. Although these data remain the cornerstone of treatment decisions for symptomatic patients, many assumptions are necessary for applying these data to the elderly population.

In the NASCET severe stenosis (>70%) group, a statistically beneficial result from surgical treatment was seen at the 3-month follow-up. Therefore, patients with symptomatic carotid disease would be expected to benefit from surgery if their operative risk was acceptable and their life expectancy was at least 3 months. Obviously, most patients treated surgically would be expected to have a life expectancy of at least 3 months. Therefore, the main issue of the decision to treat elderly symptomatic patients rests in the estimation of operative risk.

The operative risk associated with carotid disease centers on two factors: stroke risk and cardiac risk. Either factor may result in morbidity or mortality, but most studies report their results as a combined risk of stroke or death after endarterectomy. American Heart Association (AHA) guidelines [75] suggest that the upper limits for an acceptable stroke/death rate after carotid endarterectomy for TIAs should be 5%. In the NASCET trial, it was in fact 5.8% overall. Monitoring surgeon-specific and institution-specific stroke/death rates after carotid endarterectomy is a basic requirement for recommending surgical revascularization. Many investigators have studied the stroke/death rates after carotid endarterectomy in elderly patients [76–95]. There does not appear to be dramatically increased operative risks due to age alone, as most studies support the use of surgical endarterectomy in the elderly. Nonetheless, all surgical series suffer from an inherent selection bias: patients at too high risk or who are too ill may simply never be offered the procedure, skewing the results further in favor of operative intervention. In the NASCET trial, this bias was applied equally to both groups, as the randomization occurred between medical and surgical therapy only after patient entry. Therefore, all candidates in this study were appropriate for surgical management. In retrospective studies concerning the safety of carotid endarterectomy in the elderly, these controls do not exist, resulting in potential selection bias. These data demonstrate that the stroke/death rate after carotid endarterectomy in the elderly is not significantly increased over that of a more traditional patient population.

The risk of anesthesia for carotid endarterectomy has been a topic of debate for many years. Although general anesthesia is a safe, effective technique for operations on the

carotid artery, proponents of local or regional anesthesia argue that the intensive care unit (ICU) stay [96] and overall length of stay [97] are both reduced, thus decreasing cost. The basic philosophy is inextricably bound to that of shunt usage: Surgeons who routinely shunt intraoperatively are more likely to use general anesthesia, as neurologic monitoring is optional. If selective shunting is employed, the decision to shunt rests on the detection of neurologic changes suggestive of cerebral ischemia. In the patient under general anesthesia, this can be provided by continuous electroencephalographic (EEG) monitoring using either a formal 16-lead EEG or compressed spectral array EEG. In the patient under regional anesthesia, neurologic monitoring is more direct, resulting from changes in the patient's neurologic examination while undergoing surgery. No evidence exists to support one anesthetic or shunting technique over another in the elderly patient undergoing carotid endarterectomy.

In the past 10 years, many studies have been undertaken to evaluate the role of carotid stenting in the treatment of carotid artery disease (Fig. 55.7). One of the early studies, the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) randomized 504 patients to be treated with angioplasty, angioplasty plus stenting, or carotid endarterectomy [98]. In this study, the 30-day stroke and death rate were similar in the endovascular and surgical groups. A common criticism of the CAVATAS study is the high rate of surgical morbidity and mortality: in this group of primarily symptomatic patients, the stroke morbidity and death rate was 9.9% in the surgical group. Additionally, the surgical group suffered cranial nerve injury in 8.7%, with no cranial nerve issues seen in the endovascular group. The overall conclusion from this early paper was that major outcomes were similar for both carotid artery stenting and carotid endarterectomy; nonetheless, increased minor complications were seen in the carotid endarterectomy patients.

The next major step in understanding carotid artery stenting occurred with publication of the SAPPHERE trial in 2005 [99]. In this study, 334 patients with asymptomatic carotid stenosis greater than 50% or and a cinematic carotid stenosis of greater than 80% and who were considered high-risk surgical candidates were randomized to either carotid stenting or carotid endarterectomy. While no statistically significant difference was seen in the rate of stroke and death in these two populations, when myocardial infarction within 30 days after the procedure was included as an end point, the results developed statistical significance. While the inclusion of myocardial infarction within 30 days was a nuance that had not been used in previous studies, its addition to the SAPPHERE outcomes resulted in a trend toward clear benefit to carotid stenting in high-risk patients. The study remains the cornerstone upon which carotid artery stenting was founded.

FIGURE 55.7 Carotid stent placement. Preintervention carotid stenosis (*left*), stent across stenosis (*center*), and final appearance after deployment (*right*).

A Cochrane review in 2004 evaluated the available data from five randomized trials involving 1,269 patients [100]. The conclusion from this study was that 30-day and 1-year safety data showed no significant difference between carotid artery stenting and carotid endarterectomy. Additionally, the increased rates of cranial nerve injury and minor complications were once again noted in the surgical group compared to the stent group.

Based on the data at this point, the FDA conditionally approved carotid artery stenting in high-risk patients with greater than 70% symptomatic stenosis. These criteria were then endorsed by the Centers for Medicare and Medicaid Services as accepted indications for reimbursement for carotid artery stenting [101] (Table 55.1).

Of note, since the early use of carotid artery stenting, there has been an apparent increase in the risk of stroke in those patients greater than 80 years of age. An extensive body of data access to confirm the fact that patients greater than 80 years of age are at high risk for stroke after carotid artery stenting. The reasons for this are not clear; carotid endarterectomy patients do not appear to have the same increase in risk associated with advanced age. One of the more promising explanations has to do with the amount of aortic arch calcification: those patients greater than 80 years of age typically have an increased amount of aortic arch calcification involving the great vessels [102]. Negotiation of the aortic arch with a long sheath in these patients presumably results in an increased risk of atheroembolism from the calcium that collects with advanced age. While definitive data remains elusive, many studies have confirmed the statistical association of an increased stroke risk with an age greater than 80 years.

TABLE 55.1 Medicare requirements for carotid stenting reimbursement

CMS requirements for reimbursement for carotid stent placement

Stenosis > 70% using NASCET methodology
Use of both an FDA-approved embolic protection device and stent
High risk
<ul style="list-style-type: none"> • Congestive heart failure (CHF) class III/IV • Left ventricular ejection fraction (LVEF) < 30% • Unstable angina • Contralateral carotid occlusion • Recent myocardial infarction (MI) • Previous CEA with recurrent stenosis • Prior radiation treatment to the neck • Other conditions that were used to determine patients at high risk for CEA in the prior carotid artery stenting trials and studies

In summary, any patient who is symptomatic because of extracranial carotid atherosclerosis and is of acceptable procedural risk should be offered intervention. The benefits of surgical revascularization are clear-cut, with improved outcome at both short-term and long-term follow-up; in high surgical risk patients, carotid stent placement using embolic protection appears to be an equivalent treatment. The selection of patients for carotid surgery versus carotid stenting will remain in evolution for the foreseeable future.

Management of the Asymptomatic Patient

With the publication of the ACAS trial [66], many questions related to the management of asymptomatic extracranial vascular disease were answered, but many more were raised.

Although a statistically significant decrease in stroke rate was achieved in male patients with at least 60% stenosis of the internal carotid artery, this protocol was limited to a population less than 79 years old. Therefore, extrapolation is necessary to apply these data to the very elderly population. In the ACAS trial, the patient group who most significantly benefited from prophylactic carotid endarterectomy was men, with a 79% risk reduction at the 5-year follow-up. Nonetheless, in this group, the absolute risk reduction at 5 years was only 8%, yielding a yearly risk reduction of only 1.6%. Given this modest risk reduction, the procedure-related stroke/death rate of 2.3% becomes an important determinant of the overall benefit. If the operative morbidity and mortality of carotid endarterectomy are excessive, the benefit is reduced further, and the overall efficacy reduced. Once again, the surgeon-specific and institution-specific risks must be accurately defined prior to recommending intervention. Similarly, the risk of operation in any given patient must be considered carefully, as any increase in operative stroke or death risk tempers the benefits seen. The stroke/death risk of cerebral angiography in the ACAS trial was surprisingly high at 1.2%. Therefore, the routine use of angiography further elevates the morbidity and mortality, potentially compromising the benefit of endarterectomy. Currently, many centers have adopted new strategies to lower the risk of carotid intervention in asymptomatic individuals. Foremost in this strategy is the elimination of routine arteriography prior to carotid surgery. Angiography is reserved for patients in whom unexplained findings are present on preoperative duplex ultrasonography. Using this strategy of selective angiography, preoperative arteriography can be avoided in up to 85% of the patients, lowering the risk of angiography (by extrapolation of ACAS data) to less than 0.2%. The loss of routine preoperative angiography in carotid surgery has two risks: failure to diagnose tandem intracranial or proximal lesions and failure to diagnose the high carotid bifurcation preoperatively. The risk of tandem lesions resides in the limitations to flow imposed across a fresh endarterectomy by a proximal or downstream lesion. Nonetheless, the risk of stroke following endarterectomy has not been documented to be higher in patients with tandem lesions [103, 104]. Similarly, tandem lesions do not seem to impose an increased stroke risk after successful extracranial carotid endarterectomy [105, 106]. Therefore, the risk of surgery and the risk of subsequent stroke are not significantly increased by the presence of tandem lesions. It appears that tandem carotid and intracranial stenosis occur in less than 10–15% of patients with carotid stenosis [107], implying that angiography contributes little to the management of most of these patients [108, 109].

The relative risk imposed by a high carotid bifurcation is much more difficult to define. Although numerous strategies have been developed to assist the surgical approach to the high carotid lesion, none has been without complications. The incremental benefit of knowing preoperatively that the bifurcation is higher than usual resides in the ability to

change the surgical approach to compensate for the anatomic variation and improve the ease of operation. Because there does not appear to be a widely accepted alternative to the conventional approach, the preoperative diagnosis of a high carotid bifurcation serves only to provide a psychological advantage to the surgeon rather than a physical one. No data exist to justify the use of preoperative angiography or duplex ultrasound to define the high carotid bifurcation.

Although operation for asymptomatic carotid stenosis is an accepted technique, particularly in the male patient, there clearly are questions about who should undergo this treatment option. Foremost in this regard is the estimation of the patient's life expectancy. If an annual benefit of 1.2% stroke reduction is to be realized with surgery compared to medical management, the longer the patient survives after endarterectomy, the greater the benefit of operation. Similarly, as discussed above, if the patient is at high risk during surgery (for any reason), the annual benefit of surgery decreases. Therefore, patient selection for asymptomatic carotid endarterectomy requires consideration of the patient's risk during operation and the patient's overall health and life expectancy. If for any reason the patient's risk during operation is increased, medical management should be considered. Likewise, if the patient's health is so fragile that reliable long-term life expectancy cannot be assumed, medical management may be the best option.

In an in-depth cost analysis of carotid endarterectomy for asymptomatic disease, Cronenwett and colleagues estimated the cost-effectiveness of carotid endarterectomy with advancing age [110]. Although the cost-effectiveness of carotid endarterectomy under age 72 seemed conclusive, the costs increased exponentially to age 79 where the cost-effectiveness was marginal. By this algorithm, carotid endarterectomy for asymptomatic disease would not be considered cost-effective at age 80 or above. This is a theoretic issue related to an "average" elderly population. Obviously, some elderly patients have sufficient long-term survival to warrant carotid endarterectomy. Others just as obviously are medical candidates only. The difficulty remains in those in-between cases where selection criteria and operative risk are not clear-cut. In these situations, an in-depth analysis of risk and benefit is probably secondary to a truly informed consent discussion with the patient and family. In this way, the ultimate decision is left to the individual most directly involved, with the surgeon providing guidance where appropriate.

The treatment of asymptomatic patients with carotid stenting is significantly more controversial. While the use of carotid stenting in high-risk symptomatic patients is accepted, its use in high-risk asymptomatic patients is problematic. Traditionally, the surgical treatment of asymptomatic carotid disease has been limited to good-risk patients with an acceptable 5-year life expectancy based on the results of the ACAS trial. Given the limitations to treatment of good-risk asymptomatic patients, defining a high-risk group has been controversial. Nonetheless, there are probably some groups worthy

of consideration for treatment in high-risk asymptomatic patients. Specifically, high risk based on anatomic criteria such as neck irradiation or previous neck surgery will define a population that may have an acceptable long-term life expectancy but has increased risk of local complications with surgery. Less well defined are the high-risk anatomic criteria associated with surgical intervention such as the presence of a high carotid bifurcation or the presence of a contralateral carotid occlusion. At the present, treatment of asymptomatic carotid stenosis is restricted to carotid endarterectomy except as part of an approved clinical trial.

Special Issues Related to Aging

Although carotid disease in general increases with increasing age, certain issues arise with aging that require further discussion. All of these problems can occur at any age, but the increased incidence in the elderly population requires explanation and elaboration.

Tortuosity of the Carotid Arteries

The coiling and kinking of the carotid arteries can be severe, resulting in stenosis or even complete vascular loops. The first references to carotid artery tortuosity appeared in relation to tonsillectomy, where the tortuous artery proved to be at risk for inadvertent injury [111]. The first recognition of neurologic symptoms referable to carotid artery tortuosity was during the early 1950s, with recommendations for arteriopathy of the artery to the sternocleidomastoid muscle [112]. During the late 1950s, cases of cortical stroke associated with carotid kinks were reported, with successful treatment in all cases by arterial resection [113]. From this point forward, the standard treatment of carotid coils has been resection or advancement of the redundant artery, which continues to be the treatment of choice today.

For a number of reasons, the exact incidence of extreme tortuosity of the extracranial carotid arteries is difficult to determine. Many patients are asymptomatic and may never come to medical attention. This situation is further confused by the lack of standard definitions as to what constitutes a kink, a coil, or a tortuosity. Tortuosity has been defined as excessive length of an artery (Fig. 55.8). This is a relative judgment, and the lengthening of the arterial tree is limited by fixation at branch points. Therefore, elongation often results in tortuosity moving away from bifurcations. If the elongation occurs between two points of fixation, kinks or coils can occur. Kinks are defined as an abrupt change in the direction of the artery, reducing the diameter of the arterial lumen (Fig. 55.9). Coils are redundant loops of artery without

FIGURE 55.8 Example of carotid artery tortuosity.

FIGURE 55.9 Example of carotid artery kink.

luminal encroachment, lacking the acute change in direction. Both kinks and coils are subsets of the vessels exhibiting tortuosity, all of which can lead to boundary layer separation with an associated increased risk of cerebrovascular events.

Angiographic studies suggest that tortuosity is common in the carotid circulation, occurring in 31% of 1,438 consecutive carotid arteriograms in one study [114]. In the same series, coils were seen in 7% and kinks in 5%. An additional study of 1,000 consecutive arteriograms suggested a 16% incidence of kinks [115]. The incidence of kinks has been associated with female sex, advanced age, hypertension, kyphosis, and obesity [116]. Estimates have suggested that fewer than 5% of patients with carotid atherosclerosis who come to operative intervention have clinically significant associated carotid tortuosity.

As previously outlined, the main therapy for carotid tortuosity or kinking is resection and advancement of the redundant segment, often in the form of an eversion carotid endarterectomy. A detailed discussion of the techniques of resection and reanastomosis is beyond the scope of this chapter, but segmental resection of either the internal or common carotid artery, with or without carotid endarterectomy, is the standard treatment. Using this technique, successful outcomes with low-stroke rates are the norm [117]. Of note, carotid stenting is significantly more difficult in a tortuous carotid artery due to the difficulties of landing the stent within a relatively straight segment of the artery.

“Dizziness” and Other Global Symptoms

The incidence of dizziness, vertigo, and syncope in the elderly population is epidemic, affecting an estimated 50% of the population over 65 years of age [118]. The causes of these symptoms are myriad, including inner ear problems, vision problems, loss of sympathetic tone, and cerebrovascular disease. Of all the symptoms related to cerebrovascular disease, this one remains unlikely to be related to cerebral blood flow. Because dizziness is a global rather than cortical symptom, the extent of cerebrovascular disease must be extreme if the symptoms are to arise from atherosclerotic disease.

Typical “drop” attacks associated with posterior circulation disease relate to loss of motor function due to cerebellar ischemia, often without loss of consciousness (cortical perfusion). These episodes are rare in the absence of combined system disease; if posterior circulation vascular disease is the only atherosclerosis present, no symptoms occur. Only when posterior disease is combined with circle of Willis or carotid disease do symptoms typically occur. If only 15% of the population over age 65 have carotid disease, a substantially smaller population of these individuals would be expected to have significant posterior circulation

disease in addition. No matter how the calculations are derived, most dizziness cannot be accounted for by atherosclerotic obstruction.

Assessment for Generalized Atherosclerosis Using the Carotid System

The most readily accessible site for assessment of early atherosclerosis remains the carotid bifurcation [119]. The presence of significant systemic vascular disease can be predicted with reasonable accuracy using duplex ultrasonography to measure intimal thickness [120–127]. Therefore, as a screening tool for atherosclerosis, carotid duplex ultrasonography may play an increasing role in the future.

To measure the carotid intimal–medial thickness (CIMT), a scan of the common carotid artery is performed, being careful to avoid segments of the artery with significant disease [128, 129]. Usually, far-wall CIMT is measured and is currently the standard rather than near-wall IMT (Fig. 55.10). The distance from the intimal reflection to the medial reflection is the measurement used, and an average is generated manually or automatically over a variable distance. There are many issues with this measurement, notably that many labs have undertaken this without validation. Since many software packages are available to perform this measurement automatically, there is some reliance on this technology to yield accuracy and reproducibility yet validation studies remain lacking. For the foreseeable future, CIMT will remain an experimental tool, to be used as part of a research protocol rather than a clinically appropriate generalized screening methodology. Currently, many commercial ventures are offering atherosclerotic screening using CIMT; its current utility remains controversial, and it remains for larger studies to better define the populations that could potentially benefit from such screening.

FIGURE 55.10 Measurement of carotid intimal–medial thickness (CIMT).

Conclusions

Carotid disease is a continuing issue in the care of the elderly. The incidence of cerebrovascular disease is increasing as the population ages, resulting in an ever-greater focus on the appropriateness of vascular care in this population. Although future studies may refine the overall management of cerebrovascular disease in the elderly, the need for intervention in symptomatic and asymptomatic patients with significant carotid disease has been better defined for this form of vascular disease than in virtually any other arterial distribution. No other area of vascular disease has been subjected to the multiple large, prospective, randomized trials as has been done with carotid disease; nonetheless, more is needed. Therefore, while the utility of carotid interventions has been uniquely studied as few other procedures have, a better understanding continues to evolve. The future direction for carotid intervention clearly includes carotid angioplasty and stent placement. Nonetheless, the exact role of endarterectomy and stenting and the appropriate patient selection remains to be defined.

Chapter 56

Natural History and Treatment of Aneurysms

Michael Wilderman and Gregorio A. Sicard

Introduction and Historical Review

Any standard medical dictionary will describe an aneurysm as a localized abnormal enlarging or ballooning of a particular segment of an artery, greater than 50% of the normal caliber, commonly related to weakness in the wall of the blood vessel [1]. The most common location of an extracranial aneurysm is the infrarenal abdominal aorta. Using the above definition, an aorta with a diameter greater than 3 cm can therefore be considered aneurysmal, although normal aortic diameters vary with age, sex, and body habitus. Histologically, an abdominal aortic aneurysm (AAA) is characterized by macrophage degradation of the medial elastin lamellar architecture by metalloproteinases [2–5].

Aneurysms have been documented for thousands of years; in fact the Ebers Papyrus in 2000 BC discusses traumatic aneurysms of the peripheral arteries [6]. Antyllus, a Greek surgeon living in Rome, described the first elective procedure to treat an aneurysm using a method of proximal and distal ligation of the artery feeding the aneurysm, along with opening the sac and evacuation of its contents [7]. In the sixteenth century, a Flemish anatomist named Andreas Versalialis wrote about an abdominal aortic aneurysm in his work *De humani corporis fabrica (On the Workings of the Human Body)* [8]. It was not until 1923 when Rudolph Matas performed the successful technical ligation of a ruptured syphilitic infrarenal AAA that anyone had deviated from Antyllus's technique [9]. Since Matas's technique carried a very high mortality, other surgeons attempted various alternative therapies such as wrapping the aneurysmal wall with various materials such as fascia lata, skin grafts, polyvinyl sponge, and even cellophane, in an attempt to prevent aneurysmal rupture, along with attempting to induce aneurysm thrombosis with wires [10–13]. Unfortunately, the morbidity and

mortality of these procedures remained high and none of their results were all that good.

Alexis Carrel, the 1912 Nobel Laureate, initially reported on the contemporary technique for an open AAA repair, perfected in animals, consisting of replacing a segment of aorta with a segment from another artery or vein [14–17]. In 1951, Charles DuBost details a more successful approach using a thoraco-retroperitoneal incision to replace the aneurysmal infrarenal aorta with a thoracic-aortic homograft in a technique mimicking Carrel's [18]. In Houston in 1953, Denton Cooley and Michael DeBakey wrote of their success using an analogous technique [19]. The use of homografts was relatively short lived due to graft degeneration and subsequent graft rupture. When Voorhees et al. (1952) used a new material for vascular conduit, Vinyon-N, marked the next major breakthrough [20]. Around the same time, Blakemore placed the first Vinyon-N graft in a patient with a ruptured AAA. Sadly, this patient expired, but the graft was patent at autopsy [21]. In 1954, Voorhees and Blakemore described their results in 16 patients with AAA repaired using Vinyon-N grafts and nine patients (56%) survived [22, 23]. These advances forced companies to evaluate various types of potential arterial conduits. In 1958, Michael DeBakey's group in Houston wrote about a significant group of patients undergoing AAA repairs with knitted Dacron grafts [24]. In 1966, Creech and colleagues continued to refine the surgical procedure by introducing an endoaneurysmorrhaphy with intraluminal graft placement, the standard open technique used today [25]. Over the next 20 years, many series were reported with operative mortalities in the 10–15% range, using polyester grafts.

Prevalence, Incidence, and Risk Factors

Elderly white males are the most common patients to present with AAA. Moreover, it is age related with increasing frequency in men 60 years or older. AAA is two to six times more common in men than women, and two to three times more common in white men than African-American men.

In men, aneurysms are first diagnosed around age 50 and reach a peak incidence at age 80. In women, they tend to present around age 60, with a steady increase after that [26–28]. The incidence of developing an AAA has varied from 3 to 117 per 100,000 person years [29–32]. Lederle et al. [33] reported that 2.6% of screened patients with a normal ultrasound 4 years prior now had AAAs. They also reported an incidence of AAA of 6.5 per thousand person years. While AAAs do not demonstrate a clear genetic transmission pattern, many papers suggest that 15–20% of first-order relatives of patients with AAAs will have one themselves [34–36].

AAA tend to be related to the process of atherosclerosis. Patients who develop AAA tend to show signs and symptoms of atherosclerosis in other arterial beds, such as their coronary carotid or peripheral arteries. Thus, patients who tend to have risk factors for atherosclerosis, such as smoking, hypertension, and hypercholesterolemia, may develop AAA [37–40].

Rupture of an AAA is the tenth leading cause of death in elderly males. Although this is the case, the majority of AAAs are found accidentally and only rarely will they be symptomatic. Therefore, a ruptured AAA may be the patient's first knowledge or presentation of his aneurysm. Ruptured AAAs have an extremely high mortality (greater than 90% overall). Even patients who make it to a hospital alive will have 40–50% mortality. Thus, the chief focus of AAA therapy is to treat in advance so to avoid rupture. Treatment of ruptured AAAs is very costly to the healthcare industry. Breckwoldt et al. found that emergent interventions for patients with ruptured AAAs led to hospital losses of \$24,655 [41]. A report of Great Britain demonstrated that about 2,000 lives and nearly \$50 million could be saved if AAAs were repaired prior to rupture [42]. Another study from the UK found that the total costs of emergency AAA repair were 96,700.69 pounds sterling, with a cost per life saved of 24,175.17 pounds sterling. The total cost of elective AAA repair was 76,583.22, with a cost per life saved of 5,470.23 pounds sterling. Emergency intervention was found to cost five times more than an elective procedure, per life saved, per year [43].

Clinical Presentation, Diagnosis of AAA, and What to Do About It?

The most likely presentation of AAA is as an incidental finding by the patient or treating physician on physical examination, diagnostic imaging for another reason, or in the operating room at the time of laparotomy for other reasons. The most dreaded presentation of AAA is that of hemodynamic instability and rupture. Free rupture into the peritoneal

cavity is usually a fatal event, but thankfully, most patients who rupture do so into their retroperitoneum which will somewhat contain the rupture. It is this condition that is sometimes termed “a leaking” AAA. These patients may present with signs or symptoms of back, abdominal, or flank pain from the rupture or pressure or compressive symptoms relating to the hematoma compressing adjacent structures. On physical examination, the patient may have a tender pulsatile mass. Back pain can be due to erosion of the AAA into an adjacent lumbar body, although it is most often due to the presence of hematoma from the AAA [44]. Flank pain is usually due to pressure and can radiate to the left groin because of pressure on the ureter. It has been well documented that a patient can present with a contained leak without hemodynamic changes and be discharged without a thorough workup only to represent in shock, so heightened awareness is required and an elderly patient presenting with abdominal or back pain must have AAA included in any differential diagnosis.

If an aneurysm ruptures, it does not always rupture into the retroperitoneum or peritoneal cavity. AAA can rupture into the duodenum. The typical presentation of this aortoduodenal fistula is a “herald” or small upper gastrointestinal (GI) tract bleed, followed by massive exsanguinating GI hemorrhage. The classic location for this is in the third portion of the duodenum and must be evaluated in any patient presenting with a GI bleed. Other GI symptoms, such as bowel obstruction, are also possible due to a large AAA compressing the GI tract, although this is rare. AAA can also rupture into the inferior vena cava. The classic presentation of this is high output congestive heart failure associated with venous hypertension, a widened pulse pressure, a continuous harsh abdominal bruit, and lower extremity swelling.

Another, although rare, presentation is due to an inflammatory or infectious AAA. These AAA are noted to have an intense desmoplastic reaction around the infrarenal aorta that involves adjacent structures. These AAA will produce local and systemic symptoms such as malaise, fever, vague abdominal, or back pain, along with weight loss and anorexia. These patients typically have an elevated white blood cell (WBC) count and the erythrocyte sedimentation rate (ESR) will be elevated in nearly 75% of the patients. The involved adjacent structures are the duodenum (90%), the inferior vena cava (50%), and the ureters (25%) [45].

One other presentation is that of thromboembolic symptoms. Since most AAA are lined with mural thrombus, pieces can break off and travel downstream, leading to ischemia. Therefore, patients presenting with embolic type symptoms must be evaluated for the presence of an aneurysm.

Most patients with AAA are asymptomatic and with the risk, morbidity, mortality, and cost if a patient presents with a ruptured AAA, targeted screening of high-risk population has become a vital. Schermerhorn et al. report that ultrasound

screening for AAA was cost effective and beneficial for men 65–74 years of age with known risk factors such as coronary artery disease (CAD), smoking, or a family history of AAA [46]. Another study Derubertis et al. established that while women have a lower incidence of AAA than men, those over 65, with a history of smoking or heart disease are at a higher risk and should also be considered for screening [47]. Most screening programs have been developed outside of the USA [48–56]. Kim et al. published the UK results for a large randomized trial which demonstrated an early mortality benefit of screening ultrasonography for AAA which is sustained long term and that the cost effectiveness of screening improves over time [57]. Beginning on January 1, 2007, Medicare started to offer a free, one-time, ultrasound screening benefit to check for AAA's in qualified seniors. To qualify for this program, men had to have smoked at least 100 cigarettes in their lifetime. In addition, family history of AAA was an inclusion criterion for this program. Medicare linked this pared screening ultrasound to their "Welcome to Medicare Physical Exam," also known as the "Initial Preventive Physical Exam (IPPE)." This benefit became a law on February 8, 2006 as the Screening Abdominal Aortic Aneurysms Very Efficiently Act, (SAAAVE) a provision of S.1932, the Deficit Reduction Act of 2005. The ultrasound can occur anytime, but patients must have had their IPPE within 6 months of their 65th birthday. Today, many national medical societies as well as industry supporters are attempting to influence Medicare into expanding the screening test for ALL Medicare patients. 70,495 men age 65–74 participated in the Multicentre Aneurysm Screening Study (MASS) and were randomized to receiving either ultrasound screening or no screening for AAA. Of the 33,839 patients randomized to ultrasound screening, 80% actually underwent an ultrasound and 5% of the men had AAAs greater than 3 cm. Four years into the trial, 65 AAA-related deaths occurred in the screened group compared with 113 AAA-related deaths in the nonscreened control group. Although neither this trial nor any other will be able to show a significant reduction in all-cause mortality, MASS did show a 32% reduction in AAA-related mortality in the group who received ultrasound screening [56]. Given these findings regarding screening for AAA, most physicians, including vascular surgeons will screen male patients greater than 60–65 years of age, who currently smoke or have smoked in the past, along with those with a known family history of AAA. Currently, the most common manner in which patients learn that they have AAA is when AAAs are found incidentally when they are imaged, either with ultrasound, CT scan, or MRI for other diseases or symptomatology.

Once a diagnosis of AAA has been made, the question is: What is the best treatment strategy? One attempt to answer this was made by a group led by Lederle. They reported on the Department of Veterans Affairs Aneurysm Detection and

Management (ADAM) Study. This multicenter randomized clinical trial was intended to compare long-term AAA survival from two treatment modalities, immediate open surgical repair for managing all AAAs less than 5.5 cm versus observation and surveillance and open surgical treatment when aneurysm reached 5.5 cm. A total of 1,136 patients were enrolled at 16 VA medical centers. The mean follow-up time was 4.8 years. This study noted that there was no significant difference between either group in terms of long-term mortality. They concluded that there was no long-term survival advantage with early surgical intervention in patients with AAA smaller than 5.5 cm even when the operative mortality is very low. They thus recommended surveillance of small AAAs and deferring open repair until the AAA has enlarged to 5.5 cm [58].

A similar study conducted in the UK found similar results. Powell et al. reported in 2007 on the long-term follow-up of 1,090 patients enrolled in the UK Small Aneurysm Trial between 1991 and 1995 and followed for 10 years. They found no long-term survival benefit of early elective open repair of small, 4–5.4 cm, AAAs. Even after successful repair, the mortality among these patients was higher than the general population [59].

Once the adequate aortic conduit to replace the aorta was confirmed surgeons began to pay closer attention to the overall medical condition of the patient with the AAA and ways to improve the intraoperative and postoperative care in order to significantly improve perioperative and in-hospital mortality. In the last 20 years, this approach of preoperatively maximizing the health status of the patient prior to AAA open repair has significantly impacted mortality with recent series reporting <5%, 30-day mortality consistently (Table 56.1) [60–71].

TABLE 56.1 Operative mortality following elective infrarenal AAA [60–71]

Authors	<i>n</i>	30-Day mortality (%)

Bush et al. (2007)	1,580 (high risk)	5.2

While mortality has declined over the years, especially in centers with high volumes, not everyone with AAA needs an operation right away. The question is who needs an operation and who can be observed? It has been documented that the risk of rupture of a known AAA is based on its maximal diameter. Aneurysms between 3 and 5 cm have less than 1% per year chance of rupturing. Aneurysms with diameters between 5½ and 6 cm have between 5 and 10% chance of rupturing in a given year. Those between 6 and 7 cm rupture at a rate of 10–20%. Those between 7 and 8 cm have a 20–30% chance of rupturing in that year. Aneurysms found to be greater than 8 cm rupture at a rate anywhere between 30 and 50% per year. One other vital factor is rapid expansion. Those aneurysms that have enlarged by more than 0.5 cm in a given 6 months also have a higher likelihood of rupturing. Therefore, it is generally accepted that aneurysms less than 5½ cm, given the low likelihood of rupturing, can be safely followed with at least yearly ultrasound, recognizing that the growth pattern of AAA is that of discontinuous. Some studies have suggested that women with AAAs should have their aneurysms fixed at a slightly smaller diameter (between 5.0 and 5.5 cm) as compared to men. Most aneurysms, especially smaller ones, tend to grow at a rate of 0.3–0.5 cm per year [72–74]. Table 56.2 lists the rate of rupture of AAA for a given size.

If a patient has symptoms of abdominal or back pain of the patient's AAA has demonstrated rapid growth, they should probably be fixed more expeditiously, even if they do not meet absolute size criteria. Other factors that have been associated with increased expansion or rupture rate are advanced age, severe CAD, chronic obstructive pulmonary disease (COPD), female, uncontrolled hypertension, or the presence of a large volume of luminal thrombus.

A group from Dartmouth led by Mark Fillinger looked at mechanical wall stress and concluded that it is a key predictor of rupture risk for AAA. A mathematical analysis of AAA geometry, known as finite element analysis, has been suggested to be a theoretically better way to estimate wall stress and the risk of rupture. It was first performed in two dimensional shapes, then later in three dimensional shapes, and most recently actual AAA shapes obtained from CT scan data [75]. Using this model, Fillinger's group looked at three groups of patients: those who presented with a ruptured AAA, those who were symptomatic and required

urgent surgery, and those who underwent elective AAA repairs. They found that peak wall stress was significantly higher in ruptured AAA and symptomatic groups compared with that of the elective repair group comparing diameter-matched subjects. The group also realized that the location of maximal wall stress in their series was not at the site of maximal AAA diameter but rather in the posterolateral location, the site where most ruptures occur. Fillinger et al. thus concluded that peak wall stress calculated with computer modeling appears to assess risk rupture more accurately than AAA diameter alone. Fillinger et al. [76] later report that for AAAs under observation, elevated wall stress associated with rupture is not simply an acute event near the time of rupture. While these studies have been very exciting, a drawback to its widespread use is the cost and time required to make these models. Another limitation to its widespread use is that most physicians are not used to stress values. Fillinger's group has thought about creating "severe or critical" stress values similar to velocity thresholds for carotid duplex scanning. While Fillinger's colleagues do not advocate stress modeling in all patients, it can certainly add more information, especially in patients at the highest risk for surgery.

Preoperative Risk Stratification and Decision Making

The goal of therapy for AAA is to prevent aneurysmal rupture. Currently, there are two effective treatment modalities to treat AAA, and thus exclude the AAA from pressurized blood flow. The first is an endoluminally placed covered stent graft (EVAR) that can be inserted either via the femoral or iliac artery. The second is an open surgical exclusion of the AAA, along with an interposition synthetic graft. Both techniques have advantages and disadvantages, and therefore each case must be evaluated separately, based on a patient's age, comorbidities, and aortic anatomy.

If a patient is found to have a symptomatic AAA (i.e., back or abdominal pain or hypotension), urgent surgical intervention is the only true chance for survival. Stable patients can undergo cross-sectional imaging to assess their potential for an endoluminal approach, along with laboratory tests. If the patient is unstable, then the patient should be taken directly to the operating room for an open repair.

Current recommendations are to repair asymptomatic male patients with aneurysms greater than 5.5 cm or asymptomatic female patients with aneurysms greater than 5.0 cm. A vascular surgeon will determine the most appropriate treatment option by taking into account preoperative evaluations such as aneurysmal anatomy, along with the patient's age and other commodities. In 1995, a group led by Steyerberg created six independent risk factors for operative mortality

TABLE 56.2 Rate of rupture based on size of AAA

Size of AAA (cm)	Annual rupture risk (%)
≤4.0	0.3
4–4.9	1.5
5–5.9	6.5
6–7	20
7–8	30

after elective AAA repair, along with their relative risks. The most important risk factors from most important to least important were renal dysfunction and a creatinine greater than 1.8, congestive heart failure with cardiogenic pulmonary edema, jugular venous distention, the presence of ischemic changes (ST depression greater than 2 mm) on a preoperative ECG, history of a prior myocardial infarction, pulmonary dysfunction including COPD, dyspnea on exertion or prior lung surgery, older age, and female gender. Based on their findings, they report that a standard elective open AAA has a operative mortality of 5%, which could rise as high as 40% if many of the aforementioned risk factors were present, and decline to less than 3% if none were present [77]. Since that time, other studies have validated this. In 2001, Hallin et al. found between a four- and ninefold increase in mortality risk in patients with renal failure alone. They also found that CAD only had between two and a half and fivefold increase in mortality risk [78].

Another important aspect is the specific surgeon and hospital. This variability is directly proportional to the number of AAA operations that are performed by the given surgeon or center per year. Larger hospital performing more AAA operations have much better outcomes than less experienced surgeons or smaller centers [79]. In 2003, a group led by Dimick concluded that high-volume hospitals that perform more than 35 open AAA per year have a 30-day mortality of 3%, as compared to low-volume centers that have a 30-day mortality of 5.5%. They also reported that high-volume surgeons with specialty training in vascular surgery, working at high-volume hospitals have the best outcomes [80].

The first critical move in evaluating a patient with an asymptomatic AAA is a thorough personal and family history and careful physical examination. Family history is a key component of the patient's preoperative assessment. If a patient has a family history of AAA, earlier repair is warranted, regardless of the method, because their risk of rupture is higher when matched with comparable sized AAA in patients without a family history [81–83]. In addition, some basic laboratory data should be collected. These first steps should help a vascular surgeon decide what kind if any operation can or should be performed to fix this AAA. In addition, any of the preoperative risks, such as any cardiopulmonary troubles, should be optimized prior to surgery. Another key fact to think about is whether the patient's current life expectancy is long enough and their quality of life is good enough to justify an intervention.

Age has been one key variable that has shown to be statistically significant when comparing mortality among groups of patients being treated with AAA. Hertzner et al. reported on a large series of patients treated with open AAA from the Cleveland Clinic. They found that age greater than 74 years significantly affected outcomes. They found a risk ratio of 2.2 in their series in these patients [63, 84]. Others have reported

similar findings of higher incidence of adverse outcomes in patients greater than 75 or 80 years of age who underwent open AAA repairs [85–87]. Based on these results, older patients, especially octogenarians, may benefit from EVAR. Sicard et al. reported that when comparing EVAR to a conventional open repair of AAA in octogenarians, the mortality, the complication rate, and extent and gravity of these complications were higher in the octogenarian group [86]. Dardik et al. reported an in-hospital mortality of patients undergoing elective AAA repair of 3.5%. However, in his series, the death rate for patients in their sixth decade was 2.2% compared with 7.3% in octogenarians [79]. These findings may sway a vascular surgeon to treat an octogenarian via EVAR if possible.

To decrease overall operative mortality, perioperative cardiac optimization is vital, especially since CAD is the main cause of early and late mortality after AAA [88]. The American College of Cardiology (ACC) has standardized preoperative cardiac evaluation for noncardiac surgery, based on their best long-term data and created categories for the risk of the procedure and the clinical risk to the patient. Patients with unstable coronary syndromes such as acute or recent MI (less than 30 days) or unstable angina, decompensated CHF, significant arrhythmias such as high-grade AV block or symptomatic ventricular arrhythmias, or severe valvular disease are considered to have major cardiac risks. Those patients with intermediate risks would have symptoms such as mild angina, prior MI by history or the presence of Q waves on an ECG, compensated CHF, insulin-dependent diabetes mellitus, or renal insufficiency. Those patients with minor risk factors include those who are of advanced age, have an abnormal ECG (left ventricular hypertrophy and left bundle branch block), have a history of a prior stroke, or have uncontrolled hypertension [89].

Van Damme et al. from Europe reported on 156 patients prospectively, assessing cardiac risk before vascular surgery. They found that in patients without clinical markers of CAD, noninvasive cardiac testing did not predict cardiac complications. In patients with definite clinical or ECG evidence of CAD, a dobutamine stress test provided additional information and optimized risk stratification. Moreover, they found that a negative stress test had a high negative predictive value [90]. In 2006, Poldermans et al. reported for intermediate risk patients, cardiac testing can be safely omitted, provided that patients are treated with beta-blockers to keep their heart rates until tight control [91]. Recently, the coronary artery revascularization prophylaxis (CARP) trial in patients with CAD and stable cardiac complaints compared preoperative coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention versus no coronary revascularization in preparation for major vascular surgery [92]. Five hundred and ten patients were randomized and 258 were assigned to a strategy of

preoperative coronary revascularization, while 252 received no revascularization procedure. Coronary revascularization prior to elective vascular surgery did not improve long-term survival. In addition, there did not appear to be any reduction in postoperative myocardial infarctions (MI) or deaths in the revascularized group. One other report from Kertai et al. looking at 570 patients found that statin therapy lowered the incidence of the composite endpoint of MI or death from 11 to 3.7% [93].

Fleisher et al. reported on the latest ACC/American Heart Association (AHA) Guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery. They determined that successful evaluation and management requires teamwork and communication. The group felt that indications for cardiac testing and treatments are the same as in the nonoperative setting, but the timing of such evaluations is dependent upon the urgency of the surgery, patient risk factors, and surgery specific considerations. The use of testing, both invasive and noninvasive should be limited to those that affect patient management. In addition, they concluded that the preoperative evaluation was their first cardiac risk stratification, both short and long term, and treatment strategies could be implemented to reduce a patient's long-term risk [89]. This study has also concluded that perioperative beta blockade is crucial for pre-, peri-, and postoperative cardiac protection.

Even though CAD and cardiac risk stratification are the number one risk for aortic surgery, other conditions need to be evaluated, too. Patients who smoke should be encouraged to stop smoking before surgery. Patients with a history of pulmonary insufficiency require preoperative pulmonary function testing. Some patients with severe bronchospastic pulmonary disease may even need to be optimized with bronchodilator therapy or steroids prior to open AAA repair. If a patient requires persistent continuous oxygen therapy, he may not be a suitable candidate for an open surgical repair.

If a patient has a history of having a stroke or transient ischemic attack (TIA) or if a carotid bruit is present on physical exam, a carotid duplex scan should be performed. If a high-grade stenosis is found in the internal carotid artery, carotid revascularization should precede elective AAA repair.

Some centers routinely perform arteriography on patients with AAA to better determine certain anatomic factors prior to deciding which technique to perform to treat the AAA. In patients with hypertension and chronic renal insufficiency where renovascular disease may be present, better renal artery anatomy needs to be known. Also, patients with claudication may need some anatomic evaluation to assess the level or levels of disease. In addition, if there is some history of mesenteric ischemia or the AAA is in close proximity to the renal arteries, better visceral vessel anatomy is required for preoperative planning. Today,

depending on the center, some of today's high-quality CT scanners or MRI machines can be as useful as traditional arteriography.

Surgical Techniques

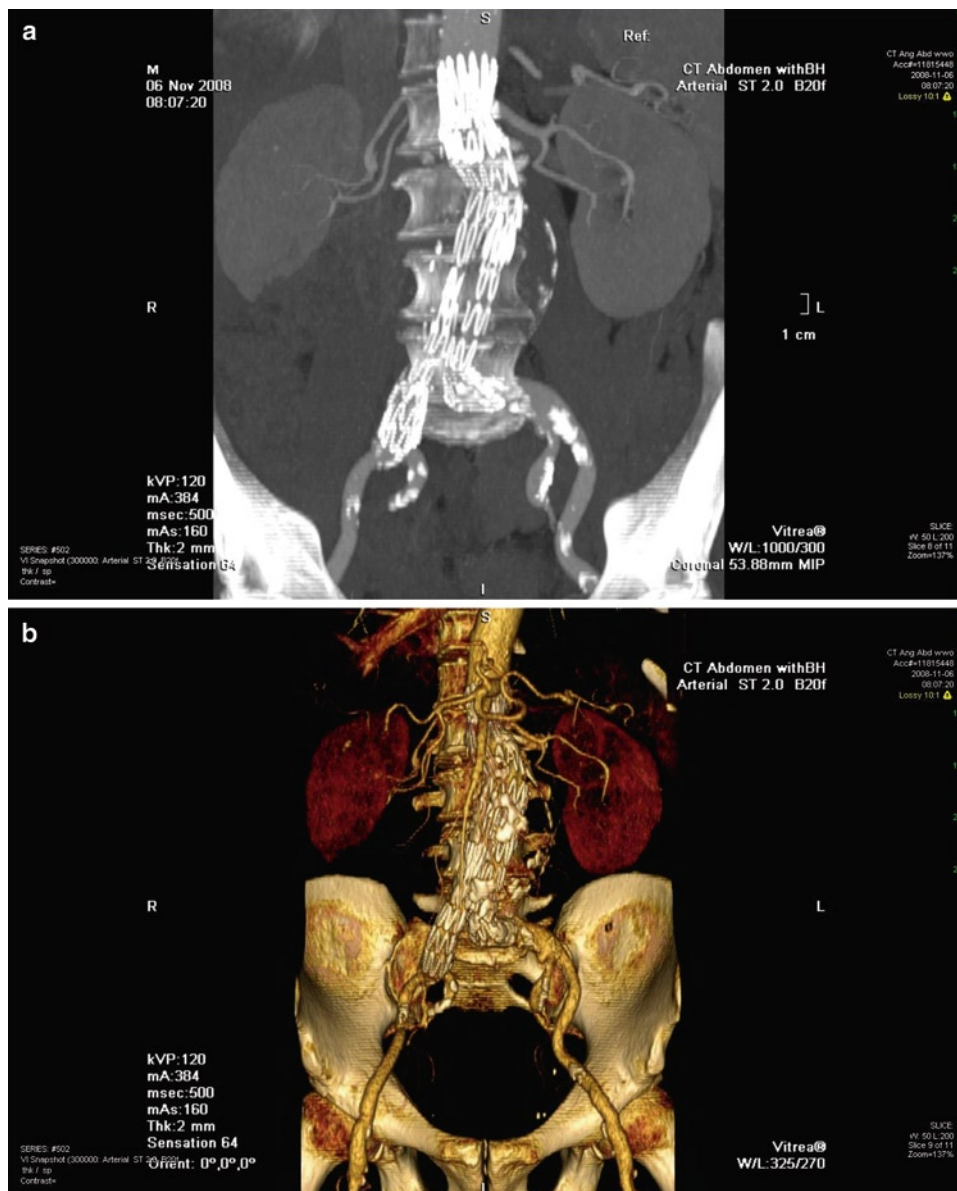

The principal aim of surgical intervention is to eliminate aneurysmal flow and wall tension, thus preventing future dilatation and rupture [94]. There are two basic approaches to treating AAA, the older more traditional open surgical repair and endovascular repair of abdominal aortic aneurysms (EVAR). To date, open repairs have proven to be more durable long term and require less follow-up than endoluminal repairs, as long as patients can tolerate the open surgery. Conrad et al. reported in 2007 on a large series of AAA from Massachusetts General Hospital and found that open AAA repairs are safe and durable with an excellent 10-year survival in patients less than 75 years. In addition, the freedom from graft-related reintervention is superior to EVAR [95]. A large series published by Hertzler et al. also showed a low 30-day mortality and excellent long-term survival with open AAA repair [63]. One issue for today's younger vascular surgeons and current vascular surgery residents (VSR) is the fact that with newer and better endovascular devices, fewer open infrarenal AAAs are being performed each year. From 2001 to 2005, the mean volume of elective open infrarenal AAA repairs declined by 27%. During that same period, EVAR procedures for the VSR have increased by 212%.

A model was created by Barnes et al. to predict outcomes for EVAR using the following preoperative variables: age, aneurysm size, ASA class, gender, preoperative creatinine, aortic neck angle, infrarenal neck diameter, and infrarenal neck length [96].

Endovascular Repair of Abdominal Aortic Aneurysms

Over the past 15 years, EVAR has become widely accepted as a means of treating aneurysms located in the infrarenal portion of the aorta. In addition, as more endovascular grafts with broader applications become commercially available, the number of EVARs performed worldwide continues to increase. A group led by Parodi et al. reported of the first endoluminal repair of AAA in 1991 [97]. Since that time, numerous devices have come to market and numerous clinical trials have been published [61, 65, 67–71, 98–100]. Endoluminal methods allow the surgeon to access the arterial system from the femoral arteries, rather than requiring a

FIGURE 56.1 (a and b) This two CT scans demonstrate a completed EVAR with the graft in proper position.

deep and extensive pelvic dissection, with its associated potential complications. This approach is even more useful in patients who are at high-operative risk due to significant medical comorbidities, prior abdominal or pelvic surgery, abdominal or pelvic radiation, lower abdominal stomas, or morbid obesity [101]. Endovascular repairs have been shown to reduce operative morbidity, mortality, length of hospital stay, and postprocedure disability [102]. The basic technical procedure involves placing an endovascular graft across the AAA below the renal arteries and above the hypogastric arteries and exclude it from arterial blood flow and systemic arterial pressure (Fig. 56.1a, b). This type of repair requires at least a 2 cm landing or attachment zone of normal infrarenal aorta above the graft and enough common iliac distal to

the aneurysm to achieve an adequate seal. Two randomized trials, EVAR-1 and DREAM trials, demonstrated a significantly lower mortality for EVAR when compared with open repair, but a higher reintervention requirement for EVAR [68, 69]. Both trials still support treating even low-risk surgical candidates with EVAR. Another report by Sicard et al. looked at EVAR as a long-term solution for patients at high risk for open surgery. The group found the EVAR for large AAA using FDA approved devices is safe and provides long lasting protection from AAA-related mortality and is certainly comparable to open repair at 4 years after the procedure [70]. Table 56.3 lists the results from the pivotal trials for each of the five current commercially available devices [103–107].

TABLE 56.3 Results from pivotal trials of long-term follow-up of each of the commercially available devices

	AneuRx (medtronic) (%)	Excluder (WL gore) (%)	Zenith (cook) (%)	Powerlink (endologix) (%)	Talent (medtronic) (%)
Freedom from rupture (at 5 years)	96.8	99.8	100	100	98.2
Freedom from conversion (at 5 years)	92.2	97	98.2	97.9	99.1
Freedom from aneurysm-related death (at 5 years)	96	98.2	97.8	97.9	96.5
Migration (at 5 years)	6.4	0.5	0.4	4.3	0.8% at 1 year not followed any longer
Probability of survival (at 5 years)	60.1	70	83	78.1	71.1

Open Technical Considerations

Once a patient and physician have agreed on an open repair, and the patient has been deemed medically suitable for open surgery, the specific approach and operation is individualized and based on a few factors. CT scan imaging provides the best method to assess the anatomical factors that will influence the open repair. The most critical is the shape and configuration of the aneurysm. The neck, the portion of the aorta immediately below the renal arteries, along with the iliac arteries must be assessed. If the iliac arteries have significant occlusive disease, the graft may have to be sewn to the femoral arteries. Another factor is the patient's pulmonary status because some approaches may be better if the patient has severe COPD. Finally, has the patient had other surgeries in the past, and if so, what types of surgery. These factors, along with operator comfort, will determine which approach is utilized. The two most frequently used incisions are a left retroperitoneal incision and a midline incision from the patient's xiphoid to his pubis. A transverse incision has also been described, especially for patients with multiple upper abdominal surgeries.

When AAA is repaired via the transabdominal approach, the patient is placed in a supine position. After entering the abdominal cavity, a full exploration of the abdominal contents should occur to rule out other intra-abdominal pathology that might have not been visible in the CT scan. If an unexpected lesion is discovered, it must be evaluated and a surgeon must make a judgment as to how best to proceed. Our group and others strongly discourages combining a sterile vascular case with a potentially contaminated gastrointestinal case.

The next step is to superiorly retract the transverse colon and greater omentum. The small bowel is eviscerated to the right side of the abdomen, thus exposing the base of the mesenteries of the left colon and the small intestine. The posterior peritoneum is then incised from the ligament of Treitz to the aortic bifurcation, thus exposing the infrarenal aorta (Fig. 56.2). To identify the neck of the AAA, the peritoneum should be incised until at least the level of the left renal vein crossing. In rare occasions of juxtarenal aneurysm, the left renal vein can

FIGURE 56.2 This drawing depicts the view of AAA via a transabdominal approach. The small intestines are mobilized to the patient's *right* and the left colon is reflected to the patient's *left*. The retroperitoneum has been opened, exposing the AAA.

be divided close to the IVC and/or reanastomosed if indicated. If the left renal vein is divided, it is important to preserve the left gonadal and adrenal vein to preserve left renal function. Once an adequate area proximally is exposed to cross clamp, the iliac arteries must also be exposed for cross-clamping. If the aneurysm involves one or more than one iliac, the dissection must be extended to the bifurcation of the common iliac(s) assuring identification of ureters and parasympathetic pudendal fibers. Usually circumferential aortic or iliac dissection is not necessary and may avoid venous injuries. One other key is constant communication between the surgical and the anesthesia teams to aid in proper intraoperative management.

Once clamps are applied, the aneurysm sac is then opened longitudinally and the mural thrombus should be removed. AAA with an adequate infrarenal neck to apply a clamp to

FIGURE 56.3 This drawing depicts a completed repair of the AAA using a tube graft.

that returns to a normal size proximal to the iliac bifurcation can have a tube graft sewn. One should use a bifurcated graft if the iliac arteries are aneurysmal. If more extensive iliac disease is present, other more complex options exist. The femoral arteries should be routinely avoided as distal landing targets to decrease the risk of wound and potential graft infection (Fig. 56.3).

Prior to removing all of the clamps, it is important to back bleed the iliac system and flush any residual or remaining debris out of the graft. After hemostasis is achieved, distal pulses should be assessed prior to beginning the closure. Typically, the aneurysm sac and then separately, the posterior peritoneum are closed over the graft in an effort to prevent intestinal contact with the aortic graft. The abdomen wall is then closed.

Many surgeons are more familiar with and thus prefer this approach to treat AAA. In addition, the transperitoneal method enables the surgeon the best exposure of the aneurysm, the renal arteries, both iliac, and both femoral arteries. This approach can be challenging in a patient who has undergone multiple prior abdominal surgeries and has a great deal of adhesions. In addition, juxta or suprarenal extension, the presence of ascites or inflammatory aneurysm can be challenging with the transabdominal approach.

FIGURE 56.4 This drawing depicts the exposure and incision for a retroperitoneal approach for an open repair of AAA.

Other surgeons prefer a retroperitoneal approach for repairing AAAs. The aorta is a retroperitoneal structure and avoiding the intraperitoneal contents is preferable in certain circumstances, especially in patients who have had prior intra-abdominal surgery. Typical situations where this approach is taken are a “hostile” abdomen secondary to multiple abdominal surgeries and adhesions, previous radiation therapy, abdominal wall stoma, a horseshoe kidney, or the need to extend the repair above the renal arteries. A left-sided retroperitoneal incision from lateral rectus margin up through the 11th or 12th intercostal space provide great exposure to the infrarenal juxta and suprarenal portions of the aorta (Fig. 56.4). A surgeon using this approach is limited in his exposure to the right renal artery, the right distal common iliac artery, and partially the right femoral artery. Also, any intra-abdominal pathology may be missed because the peritoneum is not entered. For a retroperitoneal incision, the patient is positioned in the right decubitus position and remains in that position with the assistance of a vacuum assisted bean bag device. The precise location of the incision depends on what procedure is planned. For an infrarenal or aorto-iliac exposure, the surgeon should make an incision medial but at the level on the umbilicus just lateral to the medial border of the rectus abdominus muscle. Based on the patient’s size and body habitus, the incision should be extended in a curvilinear fashion superiorly and posteriorly to either the 12th rib or the interspace between the 11th and 12th ribs.

The peritoneum is mobilized until the left ureter and left gonadal vein are identified. The left ureter is then dissected and mobilized from the level of the renal pelvis down to the

iliac artery bifurcation, looped with a vessel loop, and gently retracted medially to avoid an avulsion or traction injury. Care must also be taken not to devascularize the ureter, which can also lead to an ischemic injury. The gonadal vein is then dissected up to its insertion into the left renal vein and typically divided. Failure to ligate the gonadal vein can lead to avulsion injuries and further bleeding. Usually, both common iliac arteries can be dissected to allow for clamp placement. If the right common iliac artery is involved with aneurysmal dilatation, intraluminal control of the right iliac system can be accomplished with a balloon catheter. The use of self retaining retractors is also vital because it facilitates exposure and avoids unnecessary trauma to intra-abdominal organs, especially the spleen. The clamping sequence is the same as for a transperitoneal approach, the iliac arteries first, and then the proximal aortic clamp is applied.

Based on a patient's anatomy, either a tube graft or a bifurcated aortobi-iliac graft can be sewn into place. If an aortobifemoral bypass is required, we prefer to suture the common iliac arteries from within the aneurysm sac. We would complete the aortic anastomosis and then rotate the table to provide better access to both groins. A tunnel is made carefully directly on top of the iliac arteries and ureters from above and on top of the femoral arteries from below. It is critical to ensure that both femoral limbs are passed posterior to the patient's ureters to avoid ureteral injury or compression. The femoral anastomoses are usually performed in a standard end to side fashion. Once hemostasis has been achieved, the aneurysm sac is closed over the graft, if possible, and the abdominal lateral wall muscle and fascia are closed in two layers.

The two main complications specific to this approach are wound bulges or hernias and chronic incisional pain. LaCroix reported on a large series and found that only 5% had an incisional hernia, but 28% had a 2 cm or larger incision bulge [108]. Our group looked at more than 1,000 patients who underwent retroperitoneal approaches for AAA. Many described some level of incisional pain that ultimately resolved after 12–24 months, but fewer than 1% required nerve blocks to relieve the pain [109].

Postoperative Complications

AAA repair, regardless of the approach, does have its share of associated complications. Many patients undergoing EVAR are sent to a regular monitored floor and can be discharged the next day. Most patients undergoing an open AAA are followed immediately in an intensive care unit, with dedicated intensivists. Many patients will need some period of continued mechanical ventilation. Careful monitoring is also crucial to monitor fluid shifts, pain control and hemodynamic

responses. Patients should have full laboratory values checked immediately postoperatively and any abnormalities, especially coagulopathies corrected immediately, along with ensuring adequate patient core body temperatures in the normal range. In addition, patients should have an ECG and a chest X-ray performed.

The perioperative complications from open AAA repairs can either be due to graft problems, such as bleeding, embolization, thrombosis, or kinking or due to organ system problems.

The most common organ complication is related to the heart and has been reported to as high as 15%, including arrhythmia, infarction, and congestive heart failure. In one series by Ali et al., which observed 43 consecutive patients who underwent elective open AAA repairs, found that 47% had troponin elevations postoperative, although only 26% met the criteria for a myocardial infarction [110]. Another study by Elkouri et al. reported on a large series of patients undergoing elective AAA repair and found cardiac complications in 22% [111]. Cardiac complications are certainly less in patients undergoing EVAR [68, 69, 71, 99].

Perioperative renal failure predicts a worse outcome. Preoperative renal dysfunction is the greatest predictor of perioperative or postoperative renal complications [112, 113]. Walsh et al. reported that in EVAR, perioperative renal dysfunction is attenuated. However, dialysis rates after EVAR are similar to those after open surgery. EVAR patients develop progressive deterioration in renal function, of unclear etiology, over time. It is most likely, multifactorial, including embolization, continued contrast media, and along with graft misplacement. They also felt that although the exact effect of a transrenal endograft fixation on long-term renal function is unknown, it may be associated with a significantly increased risk of renal infarction [114]. In open repairs, care must be taken to ensure adequate kidney perfusion to reduce this complication. Intraoperative measures, such as careful clamp placement to avoid renal embolization and flushing the proximal anastomosis, will aid in this. If flow to a kidney is halted for more than 30 min, topical packing of the kidney with ice along with flushing iced heparinized saline in the renal artery can help preserve renal function.

Pulmonary complications such as pneumonias or chronic ventilator dependence have also been reported. Elkouri also reported 16% of their patients had pulmonary complications [111]. A large series by Hertzler et al. at the Cleveland Clinic only reported 4.2% of their patients developing pulmonary complications, with the majority having pneumonia, although 1% developed adult respiratory distress syndrome [63]. Early extubation and aggressive pulmonary toilet and early ambulation can aid in preventing pulmonary complications. These complications are less for EVAR since most patients are extubated in the operating room and many of these cases are performed under spinal, epidural, or local anesthesia.

Perioperative procedure related complications include iatrogenic injuries, hemorrhage, renal and lower extremity embolization, and colonic ischemia. Hemorrhage usually results from technical problems with the proximal anastomosis or a missed arterial or venous injury. Venous bleeding is usually due to an iliac or renal vein injury during the initial exposure or clamp injury. In fact, some advocate that there is no need for circumferential dissection of the iliac vessels because the arteries can be adherent to the veins.

Colonic ischemia after AAA repair is rare, but it can be deadly and a high index of suspicion is required. A post op AAA patient with an unexplained fever, leukocytosis, and/or left lower quadrant pain, as well as, one with bloody rectal discharge should be urgently evaluated for colonic ischemia with a flexible sigmoidoscopy or colonoscopy. A study by Brandt et al. in 1997 reported that flexible sigmoidoscopy reliably predicts full thickness colonic ischemia for AAA repair. Patients with nonconfluent ischemia limited to the mucosa can be safely followed by serial endoscopic examinations [115]. Boley et al. have described three forms of ischemic colitis. In the mild version, which affects about 50% of the patients who underwent AAA repair, the ischemia is limited to the colonic mucosa and submucosa. Patients may have symptoms of abdominal pain, ileus, distention, or bloody diarrhea, but the disease process is self limited and resolves with adequate resuscitation. A worse case involves ischemia of the muscularis and may lead to stricture formation. The most catastrophic and concerning form of colonic ischemia affects less than 20% of the patients. Transmural ischemia and colonic infarction is present with free or contained colonic perforation being present. This necessitates a return to the operating room for a washout of the contamination, along with a Hartmann's procedure and a colostomy. Another issue here is graft infection [116, 117]. The overall incidence of clinically relevant ischemia has been reported to be 1–3% after elective AAA repairs, and much higher after ruptured AAA repairs [118–123]. Another study of 105 patients undergoing flexible sigmoidoscopy found colonic ischemia in 11.4% [124]. The classic presentation of bloody diarrhea in the early postoperative period only occurs in about 30% of cases [119].

AAA repair can alter sigmoid blood flow because ligation of the IMA or internal iliac artery, embolization of debris from the AAA, prolonged hypotension, or a retractor injury can affect the collateral branches to the colon. In patients undergoing open AAA repair, 50% have a patent IMA, which could be reimplanted or bypassed [125]. Most surgeons evaluate collateral colonic circulation by assessing the back bleeding of the IMA. Brisk back bleeding, along with a normal looking colon typically would indicate to a surgeon that it is safe to ligate the IMA. Several studies have shown that IMA reimplantation did not influence postoperative colonic ischemia [122, 123, 126, 127] but certainly was safe and may

be advantageous in selected patients. Preoperative imaging by CT angiography can be useful in assessing the potential need to reimplant the IMA, especially if evidence of chronic mesenteric arterial obstruction.

As for EVAR and colonic or visceral ischemia, many series report zero incidence of colonic ischemia [128–130]. Geraghty et al. reported on a large series of patients treated with bifurcated endovascular grafts. Of those, 19% underwent perioperative hypogastric artery embolization. They found that four patients (1.7%) had signs or symptoms of ischemic colitis, and three required a colectomy. All three patients who underwent a colectomy were found to have ischemia secondary to atheroemboli and all had bilateral patent hypogastric arteries. They therefore concluded that while elective embolization of one or both hypogastric arteries may contribute to pelvic ischemia and ischemic colitis, atheromatous debris rather than proximal hypogastric artery occlusion is the primary cause of ischemic colitis [131]. Another series by Mehta et al. found the incidence of ischemic colitis from endovascular repair to be less than their incidence from an open repair (2%) and also suggested that embolization was the most common cause of ischemic colitis [132].

Ureteral injury is rare, although if it occurs, it should be repaired at the time of discovery, over a double J stent using interrupted absorbable sutures. The spleen is another organ is often injured, usually because of retraction. The treatment for a fractured spleen, especially in the face of an ongoing coagulopathy is a splenectomy. Inadvertent enterotomies made during the initial opening should be repaired and the AAA portion should be aborted. One last complication that can occur, as with any wound closure, is the inadvertent capture of a piece of small or large intestine in the closure, lead to a fistula, an obstruction, or bowel ischemia.

Another complication, although usually more delayed, is sexual dysfunction as a result of injury to the autonomic nerves during the iliac dissection. It most frequently presents as retrograde ejaculation, although erectile dysfunction does occur too. Most men undergoing elective AAA repair have some component of this preoperatively. In the ADAM trial, 40% of men had impotence before AAA repair [133]. Careful dissection in the region of the distal left side of the aorta, especially near the IMA and the left common iliac artery has been shown to reduce this complication substantially, which has been reported as high as 25% [134, 135]. Another important component to preserve sexual function is the preservation of at least one internal iliac artery with antegrade blood flow.

One complication unique to EVAR is an endoleak. This refers to the persistent filling of the aneurysm sac despite the presence of a stent graft. It is the most common complication following EVAR and has been reported as high as 12–44% [136–140], but with newer grafts, the incidence is reported between 15 and 22% [98, 141–143] at 1 month. Endoleaks are divided into five types: Type I is perfusion of the sac from

CONTROVERSIAL CASE STUDY

A Complex AAA in an Elderly Patient Not Suitable for Open Repair

An 82-year-old African-American male with a past medical history of CAD, s/p CABG × 4 6 years ago and PTCA and stenting 8 months ago, COPD on home oxygen at night, and poorly controlled hypertension presents to a vascular surgeon with a palpable and pulsatile abdominal mass. The patient denies abdominal or back pain and is otherwise asymptomatic. He states that he takes a long list of medications including aspirin, plavix, coreg, lasix, lipitor, and vasotec. His physical exam other than the palpable abdominal mass is unremarkable. A CT scan is obtained that shows an 8 cm infrarenal AAA that begins less than 1 cm below the renal arteries. His iliac arteries are very tortuous and heavily calcified. This patient is clearly not a suitable candidate for open AAA surgery

and his anatomy is really unsuitable for standard EVAR techniques. Unfortunately, more and more patients present like this. What can be done for this and other patients like this? Some surgeons would attempt an open repair and hope that the patient can pull through it, although the patient would be at significant risk for postoperative cardiac or pulmonary complications. Others would try EVAR and potentially sacrifice one of the patient's kidneys and risk placing the patient on dialysis. Another option would be to refer the patient to one of the two or three centers in the country that can perform EVAR with the use of fenestrations (holes) or branches in the graft to allow for the preservation of the renal or visceral arteries. One final option is not to recommend any therapy. A discussion with the patient and his family would then need to occur describing the fact that the patient is at high risk for rupture but no one can predict when this may occur and some of his other comorbidities may lead to his death before his AAA. There is no correct option.

a proximal or distal endpoint due to inadequate fixation; type II is retrograde perfusion of the sac via collateral flow; type III is antegrade perfusion of the sac from a leak between components; type IV is antegrade perfusion from holes within the graft material; type V is serum transudation into the sac through the graft material. Type I and III are the most worrisome and require treatment rather urgently. Type II leaks are the most controversial. The majority will thrombose spontaneously over time. Many remain patent, but intervention is typically only indicated in the leak is associated with AAA enlargement [144].

Another unique complication of EVAR is graft migration after implantation. There is significant variability depending on the commercially available graft and over time with newer products, the incidence has been decreasing [98, 141, 143, 145].

One other complication related to EVAR is access-related injuries such as arterial dissection, rupture, thrombosis, pseudoaneurysm formation, and lymphocele. Each graft company has a unique set of complication rates from their IDE trials [98, 141, 143, 145].

One other dreaded complication with a very high postoperative morbidity and mortality is spinal cord ischemia and paralysis. This is much more common after thoracoabdominal or suprarenal AAA repairs, rather than infrarenal AAA repairs, because the accessory spinal artery normally takes off the aorta in the chest or proximal abdominal aorta, although it has been reported. These reports have

stressed the value of preserving pelvic collaterals and internal iliac arteries if at all possible. Occlusion or division of these vessels combined with periods of severe hypotension can lead to spinal cord ischemia and paralysis [146]. Paralysis has also been reported after EVAR, although far less common with an estimated incidence of 0.21% [147, 148].

It has been estimated that 30–40% of patients with abdominal aortic aneurysms (AAA) are not candidates for endovascular repair using the current commercially available devices. The primary limitation has been unfavorable anatomy most often associated with the proximal aortic neck. Aortic necks with large diameter (>32 mm), severe angulation (>60°), a reverse taper or cone-shape, a short seal zone (<10 mm), or an absent infrarenal neck are not candidates for the currently available devices and open repair is the best option for those patients [149–154]. The mortality associated with conventional treatment of open pararenal and suprarenal aneurysms ranges from 2.5 to 8% [63, 111, 155–157] and for thoracoabdominal aneurysms is from 5 to 34% [158–162]. In addition, open surgery is associated with significant morbidity rates from 20 to 40% [157]. Notable complications include paraplegia, mesenteric ischemia, renal failure, cardiopulmonary complications, and wound complications [158–162]. This is even more relevant for elderly patients. While some may tolerate major open aortic surgery many will not, mainly because of poor cardiac or pulmonary function. Therefore,

some other strategies are necessary to treat these patients effectively.

While not widely available nor approved in America for everyone's use, complex endovascular repairs involving the visceral segment do occur. These can be divided into two broad categories. A fenestrated endovascular repair is when a device is used to treat an aneurysm with an inadequate neck, yet the visceral vessels arise from a segment of normal aorta and the added length is required to provide an adequate proximal seal and secure attachment. Fenestrations are actual holes in the graft and vary in size depending on the need of a particular patient. Although fenestrated stent graft repairs do not typically require branches to ensure a tight seal, most visceral branches are stented open using balloon expandable stents to ensure proper alignment of the graft and the particular visceral branch vessel. Scallops are openings cut at the proximal end of a stent graft to allow for further extension of the graft cephalad, surrounding and encroaching onto a visceral vessel without actually it [152]. Branched endovascular repairs are currently performed using one of two methods. The main device can have cuffs that act as directional branches and serve as attachment sites for each visceral artery branch involved in the repair (cuffed-branched stent graft). On the other hand, the device may have multiple branches that arise from the aortic graft proximal to the target branch and are completed with a bridging covered stent extending into the target vessel [152, 163]. Aside from two major centers in the USA, these types of operations are performed either off label or the patients are not offered treatment because of their age and other comorbidities. FDA approved trials are just beginning at a few centers in the country to treat these complex AAA in patients not suited for open repair.

Open infrarenal AAA repairs have been performed for over many years with significant improvements in clinical outcomes. This repair has proven to be extremely safe and durable, especially in centers that perform a high volume of these cases each year. Even with the increasing popularity, success, and durability of endovascular repairs, some patients will not have the correct anatomy for a stent graft and thus require an open operation, although as technology and devices continue to improve, more and more patients are becoming candidates for EVAR. The knowledge and skill to perform both open AAA and EVAR is vital for today's vascular surgeon. Moreover, the knowledge about preoperative patient selection and optimization along with some of the pitfalls that can occur intraoperatively will further cut down a patient's perioperative morbidity and mortality regardless of the method employed. In addition, a keen eye to postoperative warning signs can potentially stave off major complications and improve long-term survival.

Gastrointestinal System

Chapter 57 Invited Commentary

Courtney M. Townsend Jr.

A 92-year-old widow, who lived alone, underwent a laparoscopic right hemicolectomy for a stage IIA cecal cancer found on workup after falling while climbing stairs at her home. Past history is important because of lack of systemic disease, no prescription medications, and only one visit to a doctor (for dog bite at an age of 86) in the past 57 years. She had no nasogastric tube and was disoriented periodically for the first two postoperative days with complete clearing without treatment and transferred to a rehabilitation floor on the seventh day for 2 weeks of reconditioning. She returned home where she resumed her activity, but with caregivers living with her. She had one postoperative visit with her doctor, then no further follow-up. At an age of 98, after 2 days of failure to eat and two episodes of vomiting, she was found to have a circumferential lesion in the mid-sigmoid colon that prevented retrograde passage of barium administered by enema. She had an emergency Hartmann's resection for a stage IIIB sigmoid colon cancer. Both the surgeon and anesthesiologist remarked that they had never taken part in an operation on a 98-year-old patient. The patient had no nasogastric tube, was disoriented periodically for the first three postoperative days, which cleared without treatment,

and she was discharged to a rehabilitation floor for 3 weeks. The patient required no narcotics after either operation. She then returned to her home where she resumed her activity and died 1 month short of her 101st birthday.

Abdominal surgery in elderly patients has made great strides in the past 30 years. More and more elderly patients have no or minimal comorbid conditions so that they are much more robust. Changes in operative and postoperative management as illustrated in this case have decreased complications and shortened the length of stay. Minimally invasive procedures, lack of use of drugs in expected postoperative disorientation, reduced use of narcotics, absent use of nasogastric tubes, and early ambulation have all improved outcomes in these patients. The absence of significant systemic disease must be recognized by surgeons and anesthesiologists as evidence that these patients can undergo required operations safely. Operations or other indicated treatments should not be withheld just because of a patient's advanced age. They should be treated as the conditions require. The chapters in this section reflect the significant advances in operative treatment of increasingly elderly patients.

Chapter 58

Age-Related Changes in the Gastrointestinal Tract

Nefertiti A. Brown, Joshua L. Levine, and Michael E. Zenilman

The multitude of changes that take place in the gastrointestinal tract throughout the life of a human have various clinical and surgical repercussions. Although our knowledge of age-related changes is growing, their consequences are still the subject of much debate and controversy. One problem when assessing the effects of aging on humans is the extreme physiologic variability seen among elderly individuals. As individuals age, differences among them increase, such as those relating to the genetic distinctions, exposure to toxins, and environmental, psychological, and physical factors. Additionally, it becomes increasingly difficult and to isolate control groups of healthy subjects because the elderly commonly have multiple medical problems. Many of these illnesses, such as diabetes, tend to confound study outcomes by adversely affecting the organs studied. Another obstacle to study age-related changes involves the vast reserve capacity with which to the human body is endowed. Some areas of the gastrointestinal tract and liver are capable of handling many times the quantitative functional capacity required during normal life and compensate well for normal physiological loss with aging, which makes it difficult to detect age-related changes in function even though they may be apparent on a microscopic level.

Esophagus

In the upper third of the human esophagus, the longitudinal and the circular muscles are striated. The second third is composed of both striated and smooth muscle fibers, and the lower third is entirely smooth muscle. Normal esophageal motor function is characterized by a peristaltic wave, which begins at the upper esophageal sphincter (UES) and propagates through the striated and smooth muscle layers to terminate in closure of the lower esophageal sphincter (LES). This peristaltic wave is initiated by swallowing,

which is controlled centrally or by a bolus within the upper esophageal lumen (primary and secondary peristalsis, respectively). Activation of intrinsic peripheral control, which can function independently of the central control mechanism, helps propel the peristaltic wave forward (Fig. 58.1). The functions of the LES, which are controlled both locally and centrally, depend on various factors, including myogenic specialization, excitatory and inhibitory neural elements, and circulating hormones.

Difficulties with swallowing become more prevalent with increasing age. Problems with swallowing are multifactorial, ranging from physiologic parameters including oral, pharyngeal, and esophageal to neurologic conditions such as stroke, head injury, and other neurodegenerative diseases [1, 2]. Many comorbid conditions are involved with abnormal deglutition, which in itself carries increased complications of aspiration, pneumonia, dehydration, and malnutrition [3]. Ekberg and Feinberg found 84% of 56 healthy elderly subjects (mean age 83) to have swallowing abnormalities compared to that considered in normal young persons [4]. Evaluation of videofluoroscopy and radiographs with the subjects erect and recumbent found problems at each phase of swallowing. Altogether, 63% of the swallowing problems were due to oral abnormalities (difficulty ingesting, controlling, and delivering the bolus relative to swallowing initiation), 25% were due to pharyngeal dysfunction (bolus retention and lingual propulsion or pharyngeal constrictor paresis), 39% were due to pharyngoesophageal abnormalities (mostly cricopharyngeal muscle dysfunction), and 36% were due to intrinsic esophageal abnormalities (mostly motor in nature). Nilsson et al. compared 17 swallowing variables between young (average age 37) and nondysphagic elderly (average age 81.2) patients and found that oral transit time, pharyngeal delay time, and pharyngeal transit time in dentate elderly persons were prolonged significantly as they required more swallows to clear the oral cavity. Multiple swallows also predisposed them to increased inspiration resulting in increased coughing [5]. This lack of coordination may explain the increased incidence of aspiration that occurs with aging.

FIGURE 58.1 Movement of food through the pharynx and upper esophagus during swallowing. (a) The tongue pushes the food bolus to the back of the mouth. (b) The soft palate elevates to prevent food from entering the nasopharynx. (c) The epiglottis covers the glottis to prevent

food from entering the airway and the upper esophageal sphincter relaxes. (d) Food descends into the esophagus (reprinted with permission from Barrett et al. [96]).

Various UES abnormalities have been shown to be related to advance age. Mean resting UES pressure has been shown to be a decrease in elderly subjects, and UES relaxation is delayed [6]. Combined with the fact that the sensitivity of the cough reflex appears to be significantly reduced in elderly subjects [7] may increase the risk of aspiration pneumonia. Both increased age and aspiration are risk factors for nosocomial pneumonia, which is three times more prevalent in older age groups than in the general population [8]. Older subjects also tend to have markedly elevated pharyngeal contraction pressures, with a reduction in the duration of the upper esophageal contraction [9]. These findings help to explain dysphagia in some patients.

Presbyesophagus, or degenerating motor function in the esophagus, has long been associated with advanced age. Whether old age in and of itself is the cause, however, remains controversial. Early studies by Zboralske et al. [10] and Soergel et al. [11] found that a reduced rate of peristalsis following swallowing in the elderly is accompanied by an increase in nonpropulsive contractions. This results in discoordination of muscular activity in the esophagus. Other age-related changes found were a defect in the initiation of LES relaxation and a primary peristalsis shown by cineradiography, intraluminal manometry, and balloon kymography in nonagenarians. The studies found esophageal motor function to be disorganized and inefficient, with various abnormalities, including reduced or absent peristalsis, frequent and prominent tertiary contractions, delayed esophageal emptying, and dilation of the esophagus [11]. Radiographic evaluations on nonagenarians have also shown a higher incidence of intrathoracic LES (which normally straddles the diaphragmatic hiatus) [10].

These studies have been criticized for having included patients with diabetes and senile dementia, diseases that can contribute to esophageal dysmotility. However, a later study that controlled for these diseases but used younger subjects (70–87 years old) found decreased amplitude of esophageal peristalsis in the elderly but no increase in abnormal motility [12]. Adamek et al. confirm that age is of little significance in esophageal dysmotility. This study also showed, however, a tendency among the older subjects toward an increase in the following parameters: distal pressure amplitudes, quotient of distal and proximal pressure amplitudes, distal duration, and percentage of simultaneous waves. The percentage of propulsive waves and proximal pressure amplitude and duration tended to decrease in the subjects [13]. It should also be pointed out that the “older” subjects’ median age in this study was just 62.4 years.

The contribution of aging to presbyesophagus remains to be fully elucidated. Some evidence suggests that dysphagia and aperistalsis can be attributed to aging alone in a distinct, small group of patients. Meshkinpour et al. performed esophageal manometry in 562 patients and found that in 29 aperistaltic patients no secondary explanation was detected. Of these patients, 26 were 65 years or older and only three were 40 years and younger. They concluded that aging remains a possible explanation [14].

Another study used only healthy volunteers to evaluate secondary esophageal peristalsis, which is believed to play an important role in the volume clearance of the esophagus of ingested material left behind after a swallow. This investigation found that in healthy elderly volunteers secondary peristalsis is either absent or its stimulation is inconsistent

and significantly less frequent compared to that and younger volunteers. The frequency of stimulation of LES relaxation in response to intraesophageal air distention in the elderly was also significantly lower and that of the young. These elderly subjects demonstrated normal primary peristalsis, indicating an intact central, preganglionic, ganglionic, and postganglionic control mechanism. These findings suggest an intrinsic defect in the afferent neural pathway, reduced concentration (or absence) of tension-sensitive receptors within the esophageal wall, or both [15].

Degenerative esophageal neurologic changes in the elderly have also been suggested by the study of other esophageal functions. Graded intraesophageal balloon distension was used to evaluate the visceral pain threshold in patients older than 65 years compared to those in the young age group. Investigators found that upon inflation of the balloon 10 cm above the LES the mean pain threshold balloon volumes in the young subjects was 17.0 ± 0.8 ml of air, and for the elderly subjects it was 27.0 ± 1.4 ml ($P < 0.01$). In the elderly group, five patients felt no pain even at maximum inflatable volume of the balloon (30 ml). These data suggest an age-related decrease in visceral pain threshold [16].

Some studies have suggested neurologic loss as a possible mechanism to explain the facts in both motility and sensory thresholds. Histologic data have linked a decrease in the number of cells in Auerbach's plexus as part of the aging process in healthy elderly individuals [17]. Filho et al. showed that patients over 70 years had a decrease in the number of neurons along the esophagus compared to subjects aged 20–40 years. This decrease in number was accompanied by the increase in the size of the neurons, suggesting that compensatory growth may be an attempt to maintain neuronal density [18]. Recent studies indicate that neuronal losses occur in the myenteric as well as submucosal plexuses and are linked to the selective preservation of nitrergic over cholinergic neurons. The reasons for this specificity are unclear [19]. Despite evidence of these age-related changes, it has been difficult to show a significant correlation between these changes and clinical dysfunction. As more studies are done with a growing population of elderly subjects, this potential mechanism will be further elucidated.

Stomach

Many of the various functions of the stomach have been studied in the aging population. A brief overview of the normal stomach physiology follows.

The epithelial lining of the stomach lumen is characterized by thick folds called rugae, which contained microscopic gastric pits. The mucosal surface of the stomach and the linings of the gastric pits are composed of mucin-secreting

columnar cells. The gastric glands are contained within the gastric pits and are responsible for secreting hydrochloric acid (HCl), pepsinogen, gastrin, intrinsic factor, mucus, and various gastrointestinal hormones. The capacity of the stomach to produce HCl is directly proportional to the parietal cell mass in the glands of the body and the fundus. The parietal cells secrete HCl by a process involving oxidative phosphorylation, the final step of which is accomplished by a sodium–potassium “proton pump” located in the apical membrane. Regulation of gastric acid secretion is controlled by histamine, gastrin, and postganglionic vagal fibers via muscarinic cholinergic receptors [20].

The motor activity of the stomach is essential to digestion in both the fasting and fed states. Between meals, contractile patterns clear the stomach of undigested material, and then the stomach relaxes and expands to receive a food bolus. The meal is ground and delivered to the small intestine for further digestion. This delivery is accomplished by a complex series of muscular contractions in the proximal and distal stomach [20]. These distinct physiologic regions of the stomach must coordinate contractile function to deliver the stomach contents to the duodenum. Gastric emptying has been found to depend on the type of food it contains: liquid, solid, or fat [20].

The cumulative effect of stress and exposure to various ingested substances over one's lifetime, such as ethanol, aspirin, and toxins, made me as the stomach mucosa and atrophic gastritis, gastric atrophy, achlorhydria, and intrinsic factor deficiency. These changes are difficult to distinguish from those resulting from age alone.

Acid Production

It is generally agreed that gastroduodenal secretory function changes with increased age, but the extent and the direction of the change remains controversial. Historically, it has been accepted that acid secretion declines as a consequence of normal aging. This observation, however, was based on studies that often included subjects with medical problems rather than healthy volunteers. The studies also predated understanding of the role of the bacterium *Helicobacter pylori* in acid production. *H. pylori*, found in more than 75% of individuals over the age of 60 [21], may cause transient hypochlorhydria in acutely infected patients (Fig. 58.2). Although long-term studies have not been conclusive, epidemiologic data suggest that long-standing *H. pylori* infection may result in reduced acid secretion secondary to atrophic changes in the gastric mucosa [22].

A large ($n=437$) computer-selected family sample of the Finnish population aged 15 years or over was extensively studied in 1982 with pentagastrin stimulation and mucosal

FIGURE 58.2 Age distribution of *Helicobacter pylori* seropositivity in gastric cancer cases (bold line) and normal controls (dotted line). In the control group, the prevalence of *H. pylori* increased significantly with advancing age. In patients with gastric cancer, *H. pylori* seropositivity is >70% in patients regardless of age, reflecting that *H. pylori* infection is a risk for development of gastric cancer (from Huang et al. [97] reprinted with permission from Elsevier).

biopsies. Gastric acid output, expressed as millimoles per hour (mmol/h), mmol/kg/h of total body weight (TBW), mmol/h/kg of lean body mass (LBM), and mmol/h/kg of fat-free body weight (FFB), correlated with the changes in the body mucosa but not with those of the antrum. This investigation also found that gastric acid secretion declines with age but did not attribute this change to aging alone. Reduced acid production did, however, correlate with atrophic gastritis (Table 58.1). Male patients with normal mucosa had no significant change in acid output, and female patients with normal mucosa actually demonstrated an increase in acid production when expressed in FFB (Table 58.2) [23].

More recently, Haruma et al. in 2000 studied the relationship between gastric acid secretion, age, and *H. pylori* infection in 280 patients with various grades of fundic atrophic gastritis (FAG) and found that basal and maximal acid output decreased with increasing age in *H. pylori*-positive patients while it had no effect on aging *H. pylori*-negative patients. The authors believe that these results correlate with the increased prevalence of FAG with age, with the progression of FAG directly proportional to the rate of gastric acid secretion [24]. This finding confirms that of prior studies that compared gastric acid secretion and *H. pylori* infection in young and old patients, concluding that gastric acid secretion does not decline as the result of healthy aging [22, 25]. Only gastritis had a negative effect on acid secretion, and *H. pylori* is commonly the causative agent [24, 26].

Studies finding a correlation between atrophic gastritis and reduced gastric acid secretion during old age are supported by the knowledge of the pathophysiology of pernicious anemia. Pernicious anemia is a disease of the elderly, the average

patient presenting near age 60. With this condition atrophy of the gastric mucosa results in decreased intrinsic factor secretion (also a product of the parietal cells), leading to reduced cobalamin uptake.

Gastric Emptying

Despite the abundance of data on gastric motility, the effect of aging on gastric emptying remains controversial. The importance of this finding extends beyond the obvious morbidity it causes in affected patients. For example, the rate of gastric emptying can influence the rate and extent of absorption of orally administered drugs, thereby influencing the rate and duration of their pharmacologic effect.

Various radioisotope methods have been employed in early studies to evaluate gastric emptying in the elderly (Table 58.3) [27, 28]. Horowitz et al. used a double isotope technique on healthy young ($n=22$; age 21–62, mean age 34) and elderly ($n=13$; age 70–84, mean age 77) subjects to evaluate gastric emptying of both liquids and solids. The data showed a statistically significant delay in both among the elderly subjects [29]. A similar study found that gastric emptying of solid foods did not change with age, but a delay in liquid phase emptying was observed [30]. In another study, Moore et al. also demonstrated a delay in gastric emptying of liquids in the elderly [28]. Evans et al. used a modified sequential scintiscanning after administration of the nonabsorbable chelated radiopharmaceutical technetium 99m-diethylenetriaminepentaacetic acid ($^{99m}\text{Tc-DTPA}$) to show that the rate of emptying was significantly longer in elderly subjects. The investigators concluded that it could explain a delay in absorption of drugs with aging. This study, however, did not control for the presence of concomitant chronic diseases such as parkinsonism, hypothyroidism, transient ischemic attacks, and strokes [27].

Clarkston et al. [31] used two isotopes to evaluate the gastric emptying of solid and liquid foods. The patients were healthy young ($n=19$, age 23–50) and old ($n=14$, age 70–84) volunteers who were evaluated sitting at a 45° angle. Gastric emptying of both solids and liquids was found to be delayed in the elderly patients. This investigation also found that the elderly had reduced hunger and desire to eat after a meal, which was thought to be in effect of delayed gastric emptying.

More recently Madsen and Graff [32] studied all segments of the GI tract, using the gamma camera technique, to observe the transit of radiolabeled liquid and solid meals. Compared to young, healthy subjects (aged 20–30, $n=16$), they found that advanced age ($n=16$, age 74–85) did not affect gastric emptying or the postprandial frequency of antral contractions or transit rate of the small intestine. They did find, however, that normal aging may decrease the colonic motility.

TABLE 58.1 Relation of acid output to age, sex, and morphology of the body mucosa acid output

^aHalf life of elimination of radiolabeled foods from the stomach

Gastric emptying is regulated in part by stomach myoelectric activity, which occurs at the membrane level of the gastric smooth muscle. The electrical membrane potentials of each region of the stomach differ as measured by electro-gastrography (EGG). EGG abnormalities occur in various pathologic states of the stomach. For example, gastric dysrhythmias have been reported in patients with gastroparesis, idiopathic for diabetic peptic ulcer disease [20], functional dyspepsia (associated with tachygastric) [33], gastroesophageal reflux disease (associated with gastric dysrhythmias) [34], and chronic intestinal pseudoobstruction (associated with various gastric dysrhythmias). Despite these findings, abnormal EGG tracings alone do not necessarily correlate with symptoms.

The basal electrical rhythm (BER), or the slow wave, is a cyclic change in the membrane potential, which varies in different regions of the stomach (Fig. 58.3). The membrane potential is generated by the membrane sodium–potassium

pump. The BER is associated with minimal contractile activity and does not result in detectable gastric peristalsis. The BER in the stomach, which originates in a pacemaker located in the mid-corpus along the greater curve, is propagated through gap junctions between adjacent smooth muscle cells. Vagotomy in humans has been shown to have no effect on the amplitude, rhythm, frequency, direction, or velocity of propagation of the electrical potentials, implying that the initiation of the current is a myogenic phenomenon [35]. This finding, along with an equally ineffectual denervation of nonvagal extrinsic stomach fibers, has also been confirmed in dogs [36].

In the distal stomach and duodenum, a cyclic contractile pattern called the interdigestive migrating motor complex (MMC) exists and is characterized by four phases. The contractions are associated with a myoelectric spike of attention superimposed on the basal electrical rhythm. The spikes are associated with rapid calcium influx into the cells. Phase I is characterized by a period of quiescence,

FIGURE 58.3 Myoelectric activity from the human stomach. Electrodes 1–4 were placed in the fundus, corpus, and proximal antrum and at the antral-pyloric junction, respectively. The fundus is myoelectrically quiet. The BER is seen in tracings 2 and 3 and is associated with cyclic membrane depolarization. No contractions are associated with the BER. Rapid depolarizations of the proximal drive the myoelectric activity of

the distal stomach. The pace-maker rests on the greater curvature of the stomach at the fundocorpal border. Spike potentials are seen in tracing 4 in the region of the antrum and pylorus. They are associated with contractions and therefore, emptying of the stomach (from Hinder and Kelly [35], with permission).

phase II is irregular motor activity, phase III is regular contraction that sweep the gastrointestinal tract in a peristaltic manner, and phase IV represents a brief period of irregular activity [20].

Abnormalities in gastric myoelectric activity have been associated with various gastric maladies, although patients with EGG disturbances alone do not necessarily have symptoms. There is evidence that the normal postprandial EGG frequency is less pronounced in elderly men [37].

Some studies have shown delayed gastric emptying in the elderly, but it has been difficult to show that it is associated with any clinical deficit. Other studies have found that there is no difference in gastric emptying between young and elderly subjects. Studies that evaluated only neuromuscular changes similarly were inconclusive about clinical relevance. If aging alone results in any gastric motility impairment, it is likely not clinically relevant.

Gastric Cancer

Because the peak incidence of gastric cancer is among patients older than 50 years, it is considered a disease primarily of the middle-aged and the elderly. Gastric cancer is also of interest to those studying the elderly because although its incidence in young patients has remained consistent, that in elderly patients has increased. Also, despite similarities in young and elderly patients in terms of tumor biology [characterized, e.g., by the magnitude of overexpression of the tumor suppressor gene p53 and the increased levels of other

cellular markers, such as proliferating cell nuclear antigen (PCNA)], the survival rate after curative resection has been shown to be decreased in the elderly. Earlier studies suggested that elderly patients with gastric cancer have poorer survival than younger patients despite a similar rate of tumor extension [38], but more recent studies have shown that elderly patients do not have a worse prognosis than younger patients. Kim et al. [39] retrospectively reviewed the records of 331 patients [young groups (<36 years, $n=137$) and old groups (>70 years, $n=194$)] with gastric carcinoma who had undergone curative and noncurative resection from 1986 to 2000 (Fig. 58.4). The elderly and young patients had similar distributions with respect to depth of invasion, nodal involvement, hepatic metastasis, peritoneal dissemination, tumor stage at the initial diagnosis, and type of surgery. Based on these records, they found that at 5 years, the survival rates of elderly and young patients did not differ (noncurative: 52.8 vs. 46.5%, $P=0.5290$; curative: 67.0 vs. 60.0%, $P=0.3100$). Additional studies, such as those by Pisanu et al. compared elderly (age >75) and young subjects who had undergone curative gastrectomy and found that elderly patients have no worse prognosis than younger patients (the 5-year survival rate was 56.2% in the older group vs. 62.1% in the younger group). However, unlike younger patients, elderly patients often have more comorbidities and as such have a higher surgical risk, which, along with tumor stage and future quality of life, impacts operative planning [40]. As prognosis is dictated by tumor stage, others have postulated that the tumor is physiologically different than in younger patients as aged cells tend to undergo more methylation, apoptosis, and telomeric dysfunction.

FIGURE 58.4 Survival curves time for patients undergoing curative resection for gastric cancer (a) noncurative resection or (b) curative resection in a Korean study. The patients were stratified to young (<36 years, $n=137$,

thin line) and old groups (>70 years, $n=194$, *heavy line*). The 5-year survival rates of young and elderly patients did not differ statistically regardless of surgery type. (From Kim et al. [39], with permission).

It is for this reason that gastric cancers in the elderly tend to be poorly differentiated [41].

Loss of gastric acidity is related to an increased risk of developing gastric cancer. It is manifested in the elderly by achlorhydria, atrophic gastritis, or pernicious anemia. It can also be the result of previous gastric resection for ulcer disease. The loss of gastric acidity may permit bacterial growth of the pathogen *H. pylori*, adding another independent risk factor for gastric cancer [42]. The risk of gastric cancer has been shown to be increased fourfold in *H. pylori*-positive persons. Although this may not reflect a causative relation, infection by *H. pylori* creates an environment of chronic gastritis and intestinal metaplasia to promote neoplastic change [43].

Mucosa-associated lymphoid tissue (MALT), which progresses to MALT lymphomas, has also been linked to *H. pylori* infection. Eradication of the *H. pylori* infection by oral antibiotic therapy has been shown to result in complete remission of the disease in some patients, especially those with early stage (stage I–II) MALT lymphomas [44].

Small Intestine

Over the course of an individual's life, enormous quantities of nutrients are processed through the small intestine. This makes the small intestine a likely place for potential changes with advancing age secondary to prolonged functioning and exposure to multitudes of potential carcinogens over time. Additionally, the small intestine is an organ of epithelial regeneration, turning over its cellular population often. This unique characteristic may be involved in the physiologic changes that occur with aging.

Motility

Advanced age is associated with a decrease in body weight, reduced caloric intake, and frequent gastrointestinal complaints. In fact, as many as 15% of adults have functional bowel complaints [45]. The effect of advanced age on the motility of the small intestine, however, is still unknown [46]. One way to evaluate small bowel motility is by studying the MMC, the ordered array of myoelectric activity and muscular contractions that travel down the small intestine in an aboral direction during fasting. The four phases of the MMC can be monitored by electrical activity, muscular contractions, intraluminal pressure, and intestinal transit times.

Husebye and Engedal [46] prospectively studied 15 healthy elderly subjects (age 81–91) and 19 young healthy controls, with ambulatory intraluminal manometry performed at home. This study found all subjects to have recurrent MMCs during fasting, with similar periodicity in old and young adults ($P=0.4$) (Fig. 58.5). Duration of postprandial motility, amplitude, and frequency of contractions during phase III and the postprandial state was also preserved in the elderly subjects. Interestingly, the propagation velocity was slower (6.5 ± 0.8 vs. 10.8 ± 1.2 cm/min), and intermittent propagated clustered contractions were more frequent in the older subjects (Fig. 58.6). However, these minor-to-moderate changes were also within the range of healthy younger adults and are unlikely to have clinical relevance. The investigators concluded that small intestinal motility, for the most part, is preserved in healthy elderly subjects. Intestinal disorders such as maldigestion, malabsorption, and bacterial overgrowth should not be attributed to age-related hypomotility [46].

As previously mentioned, Madsen and Graff [32] confirmed these findings using solid and liquids meals with

FIGURE 58.5 Propagated cluster contractions (PCCs) in the small intestine during the postprandial state in an old adult. A typical sequence of repeated PCCs at intervals of 1–2 min is shown. The *bottom tracings* in both *boxes* correspond to the duodenal sensor, and the top tracings show

the recording from the proximal jejunum. These contractions are seen in increased frequency in the old person when compared with young controls (from Husebye and Engedal [46], with permission from Taylor and Francis).

FIGURE 58.6 Small intestinal transit of liquid and solid marker in 16 older and 16 young volunteers. *Horizontal bars* indicate mean values (from Madsen and Graff [32], by permission of Oxford University Press).

radionucleotide tracers in healthy elderly subjects and compared it to that of younger subjects and found that advanced age did not affect small intestinal transit time (Fig. 58.6). This is also consistent with Argeny et al. who similarly evaluated transit times in ten young and nine elderly volunteers (using ^{99m}Tc -sulfur colloid-labeled eggs) and also found no difference between young and elderly subjects. The authors did note that there was a wide normal range of transit times in normal subjects and significant intrasubject biologic variability [47]. This is not uncommon in motility studies and is an important point highlighting the small bowels reserve capacity.

Morphology

There is little data concerning structural changes with increasing age on the human small bowel. In a study conducted in 1975, the jejunal mucosa for necropsies of 32 patients under the age of 60 (mean age 43) and 39 patients ages 67–90 (means age 80) were evaluated microscopically. Only minor differences were noted in the villous morphology between the young control group and older subjects. Specifically, broader, shorter villi were found to be more common in the elderly. This led the authors to postulate that

FIGURE 58.7 Relation of the intestinal mucosal surface area to the age of the patient. An indirect statistically significant correlation is noted (from Warren et al. [49], with permission from Elsevier).

this minor difference in total villous surface explains some absorption problems with age [48].

Warren et al. compared the small intestine histology of ten well-nourished elderly patients ages 60–73 to that of ten similar patients aged 16–30. A highly significant reduction in the mucosal surface area was found in the older age group (Fig. 58.7). The mean villous height was also slightly reduced and the breadth slightly increased, but these differences were not significant [49].

Corazza et al. evaluated the small bowel mucosa of 16 elderly patients and 22 younger controls (all with abdominal symptoms) to determine the surface area/volume ratio of jejunal mucosa using microscopic pointing techniques. This technique is performed by counting the number of times the standardized lines of a reticule intersects the jejunal mucosal surface under a set magnification. The surface area/volume ratio, which is an index of the extent of the mucosal surface area, was determined. No significant difference was found between the two groups for either parameter [50]. In a later study, Corazza et al. [51] showed through immunohistochemistry that this is likely linked to increased expression of a marker of enterocyte proliferation: proliferating nuclear cell antigen (PCNA) in both the crypts and villi of the human small bowel. The immunoreactivity and availability of PCNA results in a hyperproliferative state with rapid enterocyte migration. Ciccocioppo et al. [52] also suggests that in addition to the hyperproliferative state the maintenance of human intestinal morphology in the elderly is promoted by exaggerated apoptosis resulting in cellular immaturity. While these varying cascades allow the morphology of the small bowel to

remain intact with age, these authors surmise that it may be a contributing factor to the development of malabsorption in the elderly.

The integrity of small intestinal mucosa may age along with the host. The lactulose/mannitol test has been used to evaluate intestinal permeability in humans. The test is based on the comparison of the absorption of a monosaccharide (mannitol), which is absorbed transcellularly, to a disaccharide (lactulose), which is absorbed paracellularly. The urinary lactulose/mannitol ratio after oral administration is a reproducible measure of small intestine mucosal integrity. The ratio is increased when the mucosal integrity is disrupted. In a prospective cohort using healthy volunteers, Saltzman et al. found small intestinal permeability, or “leakiness,” not significantly altered with age [53]. Riordan et al., using the same test, found that although intestinal permeability increases with small intestine bacterial overgrowth with colonic-type bacteria, this effect is independent of age [54]. Similarly, the thickness of the small bowel was found by deSouza et al. to be unchanged in the elderly. The latter investigation also found that the density of nerve cells in the myenteric plexus of the small bowel is decreased in the ages small intestine [55]. This implies that the intrinsic innervation of the human intestine is reduced during old age.

Absorption

Malnutrition in the elderly has been theoretically attributed to malabsorption at the level of the intestinal epithelium [56]. However, there is evidence that age alone does not adversely affect brush border enzymes. Wallis et al. collected 38 duodenal biopsy specimens from patients 55 to 91 years of age. Tissue was evaluated for the activity of the brush border enzymes maltase, sucrase, lactase, alkaline phosphatase, leucine aminopeptidase, and α -glucosidase. The study demonstrated no significant effect of age in the specific activities of these enzymes. It also found that glucose transport was not changed with extremes of age [58].

Using probe molecules that are absorbed by active and passive intestinal transport and are easily recovered in the urine, Beaumont et al. found no significant age-related decline in passive absorption of carbohydrate either in healthy nonhospitalized individuals or in elderly long-stay hospital residents [58]. In another study, Arora et al. investigated three aspects of intestinal absorption in the elderly and found no significant change. A series of 114 healthy adult volunteers (age 19–91) were started on a diet of 100 g of fat per day 1 day prior to testing. The subjects remained on the diet for the following 72 h as their stools were collected and

tested for fecal fat. There was no change with advancing age. In another arm of the study, 25 g of D-xylose was given orally to 54 fasting volunteers (56–86 years; 20 men and 34 women). Serum and urinary xylose levels were measured. There was no significant difference in D-xylose serum levels between young and elderly volunteers. Although urinary excretion of D-xylose in the elderly was found to be significantly decreased ($P < 0.02$), there was a concomitant decrease in the creatinine clearance with advancing age ($P < 0.01$). This suggests a decrease in renal function rather than a problem with absorption as the reason for decreased D-xylose levels in the elderly. In the third part of the study, [^{14}C] glycocholate breath tests were performed in 60 healthy volunteers [30 were ≥ 30 years (15 men and 15 women) and 30 were ≥ 60 years (15 men and 15 women)]. This test is used to assess increased deconjugation of bile salts, which suggests bacterial overgrowth of the small intestine. There was no evidence of an age-associated increase in bile salt deconjugation by intestinal bacteria [59].

Malabsorption in the elderly has been shown to correlate with bacterial overgrowth. Vantrappen et al. [60] measured intraluminal pressures at the gastric antrum and at different levels of the upper small intestine to assess the interdigestive motor complex in 18 normal subjects (ages 18–71 years) with normal $^{14}\text{CO}_2$ acid breath test and 18 subjects with abnormal $^{14}\text{CO}_2$ acid breath test. Nine patients with various digestive diseases but negative $^{14}\text{CO}_2$ acid breath tests were studied as an additional control group. All but five patients had normal interdigestive motor complexes and the five patients in whom the motor complex was absent or greatly disordered had bacterial overgrowth as evidenced by $^{14}\text{CO}_2$ bile acid breath tests. These observations show that changes in interdigestive motor complexes occur in patients with bacterial overgrowth and as such it is a possible mechanism for malabsorption absence of structural abnormalities.

MacMahon et al. [61] evaluated 30 elderly patients between 68 and 90 years of age for small intestinal bacterial overgrowth (SIBO). Advancing age correlated significantly with rising counts of strict anaerobes in the small bowel. The investigators thought that malabsorption in these patients was not related to bacterial overgrowth because metabolic or nutritional abnormalities could be attributed to alternative causes. This refutes an earlier study done by McEvoy et al. who studied 490 patients over age 65 and found that 71% of the malnourished patients (those in whom poor diet alone was not a factor) had bacterial overgrowth [62].

Fat is a major source of caloric intake, and as such its absorption is an important area of investigation in the elderly. Fat absorption is a complex process involving four major phases: (1) Intraluminal processes (digestion and solubilization); (2) mucosal uptake; (3) intracellular reesterification and lipoprotein synthesis; and (4) export for the enterocyte into the lymph. Although disruption of any of these phases

can lead to fat malabsorption, this too is rarely observed in elderly patients. In a study of 114 healthy, free-living subjects ages 19–91 years, Arora et al. found that on a diet of 100 g of fat per day, fecal fat in a 72-h collection did not increase with advancing age. Lipid digestion and absorption are well preserved in aging individuals [59].

Liver and Biliary Function

The liver is responsible for the synthesis of clotting factors and the metabolism of toxins, including anesthetics, analgesics, and sedatives, all of which are important in elderly surgical patients. The liver in adult men has been found to increase in size only marginally, from a median weight of 1,820 g at age 25 to a median weight of 1,840 g at age 55. It then decreases by 20% to a median weight of 1,480 g by age 75. The median weight of the female liver similarly changes from 1,430–1,460 g during the range of 20–60 years, to 1,180 g by 75 years (Fig. 58.8) [63]. At the microscopic level, the histology reveals a loss of mitochondria and smooth endoplasmic reticulum [64]. Blood flow to the liver is also reduced with aging. Sherloch et al. used the bromsulphalein technique to estimate hepatic blood flow in 29 men and found a decrease in flow with increasing age of about 1.5% per year. At age 65, hepatic blood flow would be expected to be reduced by about 40–45% compared with that of a 25-year-old [65]. There is some controversy as to whether a reduction in liver function with age is attributable to these physical changes or there is some intrinsic age-related cellular change [66].

In another branch of their study of 60 healthy, adult volunteers, Arora et al. performed [^{14}C] the aminopyrine breath test that measures the rate of demethylation by hepatic microsomes, thereby estimating the capacity of hepatic microsomal phase I monooxygenases. This study was unable to show a statistically significant difference between young and elderly subjects and concluded that hepatic functions are generally well preserved during the normal human aging process [59].

Many pharmacokinetic studies in human subjects have suggested that the clearance of drugs metabolized by oxidation–reduction is reduced in the elderly by 10–50% [65]. One way to evaluate liver function in aging is to study the liver's store of cytochrome P450 and its functional capacity. Sotaniemi et al. examined liver biopsy samples from 226 patients (102 women and 124 men) with equal histopathologic conditions. This was ensured by dividing the liver biopsies into three groups using standard histopathologic conditions: (1) apparently normal liver histologic diagnosis; (2) subjects with slight-to-moderate changes in the liver parenchyma (fatty liver, fatty liver with fibrosis, degree of fibrosis 1–3, and reactive changes such as granulomas or

FIGURE 58.8 Pattern of change in human liver weight with respect to age. At age 55–60, the mean weight begins to decline in both men and women (reprinted with permission from Boyd [63], Copyright © 1933 American Medical Association. All rights reserved).

portal infiltrates); (3) subjects with severe changes (cirrhosis and hepatitis). They evaluated the cytochrome P450 contents in liver biopsy samples and the plasma antipyrine (phenzone) clearance rates, which tests for hepatic drug metabolizing capacity. The study found that cytochrome P450 content in subjects 20–29 years was 7.2 ± 2.6 mmol/g; it increased during the fourth decade to 7.6 ± 2.5 (+7.2%, $P = \text{NS}$) and declined after age 40 to 6.1 ± 2.2 (–16%, $P < 0.01$), a level that remained relatively constant until age 69. It declined further to 4.8 ± 1.1 after age 70 (–32%, $P < 0.001$). The antipyrine clearance rate in young subjects was 46.4 ± 18.5 ml/min, remained unaltered during the fourth decade, and declined after age 40 by a rate of 0.34 ml/min per year toward old age (–29%, $P < 0.001$). The antipyrine half-life also changed during old age, increasing linearly from 9.6 ± 2.0 h in young subjects (20–29 years) to 12.1 ± 3.1 h in the elderly (>70 years) (+26%, $P < 0.001$). There was also a decline in the apparent volume of distribution of the drug: 0.46 ± 0.12 l/kg in young subjects (20–29 years) and after a linear decline with aging 0.40 ± 0.07 l/kg in middle-aged subjects (60–69 years) and to 0.41 ± 0.09 l/kg in the elderly (70 years) (–11%). This reduction of liver drug metabolism with age, along with a decline in cytochrome P450 content in livers of the elderly, suggests primary hepatic aging. The authors concluded that caution is advisable when using drugs metabolized by the liver in the elderly and that elderly patients should be closely monitored for high blood levels caused by reduced drug metabolism, drug interactions, or both [67]. Aging of the liver may not be readily apparent in the healthy individual; and it is often unmasked only by stress, illness, or infection.

In addition to any changes due solely to aging, the liver is particularly susceptible to the toxic effects of environmental agents such as cigarettes and ethanol. Its decline in function is secondary to decreased size and blood flow can be attributed to nonhepatic factors, such as reduced cardiac output and age-related reduction of trophic factors from the pancreas via the portal system such as insulin and glucagon [65]. Here again it is difficult to determine how much functional decline can be attributed solely to age, as the liver has a large reserve capacity, but there is some evidence of physical change.

Increasing age is known to be associated with a high incidence of gallstones in both sexes. This was confirmed by a large ($n = 1,000$) study in which multiple logistic regression was used to show that age was the most important variable associated with cholelithiasis [68]. Another study that supported this finding was the Multicenter Italian Study on Epidemiology of Cholelithiasis (MICOL). In this study, data from 29,584 individuals (15,910 men and 13,674 women) examined in 14 cohorts (with a participation rate above 50%) were collected. Increasing age was again found to be associated with an increased incidence of gallstone disease, by both univariate and multivariate analyses in men and women. Interestingly, gallstone disease was also associated with decreased serum cholesterol [69], which may be related to a high proportion of biliary cholesterol and the lithogenic index, which have been shown to be elevated in elderly women. Valdivieso et al. reported that 41.7% of elderly women had supersaturated bile compared to 8.3% of younger women [70].

Liver regeneration is known to occur after resection, and this effect has been studied in the elderly. The livers of aged rats have been found to have decreased regenerative capacity by PCNA [71] and [3H] thymidine incorporation [72]. This finding has been contradicted in human studies which found that there is no relation between advanced age and regenerative capacity.

Pancreas

Like the liver, the pancreas progressively atrophies with age. Histopathologic findings associated with it include increased ectasia of the pancreatic ducts as well as interlobular fibrosis, ductal hyperplasia, and narrowing of the pancreatic ducts [73]. Despite this, the pancreas, similar to other areas of the GI tract has enormous reserve capacity, making it difficult to attribute pancreatic changes solely to old age.

As acinar cells make up 80% of the pancreas, an effective way to assess pancreatic function is to test for exocrine output in response to infusion of secretin and cerulein. When this test was performed on 25 subjects over the age of 60, no statistically significant decrease in pancreatic output was observed compared with that in 30 young controls [74]. The same group subsequently confirmed their findings with an updated, elegant method of evaluating pancreatic function – the fluorescein dilaurate (pancreolauryl) test. For this test, subjects are given the synthetic, poorly water-soluble ester fluorescein dilaurate orally. In the duodenum, this compound is hydrolyzed by pancreatic arylesterases into lauric acid and free water-soluble fluorescein. The fluorescein is absorbed in the small intestine, conjugated in the liver, and excreted in the urine. Fluorescent activity in the urine output correlates with pancreatic function and digestive capacity. Sixty healthy elderly subjects (aged 66–88, mean age 78 years) were compared to 36 healthy younger subjects (aged 21–57, mean age 36 years). No significant differences in pancreatic function could be shown between the elderly under age 80 and those over age 80 [75].

Another way to evaluate pancreatic exocrine function is to determine serum levels of pancreatic enzymes. Carrere et al. compared immunoreactive trypsinogen and lipase in healthy elderly adults and younger adult controls. This investigation found that the pancreatic enzymes were similar in young and elderly adults, with no significant differences between the groups [76].

It has been established that humans become glucose intolerant with age. It is still somewhat controversial, though, whether this change is due to beta-cell failure, peripheral insulin resistance, or a combination of both. Discerning between each of these is difficult. Elahi et al. conducted a glucose clamp study, in which a hyperglycemic state is

induced to differentiate the intrinsic functions of beta cells from peripheral insulin resistance. Two hundred and thirty hyperglycemic clamps were done on 85 young (age 24–39), 47 middle-aged (age 40–59), and 98 old (age 60–90) subjects [the latter group was further divided into old-normal and old-impaired, based on the results of the oral glucose tolerance tests (OGTT)]. Although OGTTs were worse in the elderly group, insulin responses during the clamp were not statistically different for this group as a whole. Additionally, insulin-dependent glucose uptake, a measure of tissue sensitivity to insulin, was decreased in the old-impaired group at each hyperglycemic plateau except the highest. This finding supports the view that glucose intolerance is due to insulin resistance [77].

Alteration in beta-cell function has also been shown in the elderly. Szoke et al. examined the effect of aging on insulin secretion (first phase and second phase) and insulin sensitivity in people with normal (NGT) and impaired glucose tolerance (IGT) tests. The study pool consisted of a total of 396 subjects (266 individuals with NGT and 130 individuals with IGT) aged 20–70 years. Changes in beta-cell function and insulin sensitivity were compared using the homeostasis model assessment HOMA indexes of beta-cell function, and insulin resistance calculated from fasting plasma insulin (in microunits per liter) and glucose (in millimoles per liter) concentrations. The authors found that beta-cell function was inversely correlated with age in the normal glucose tolerance group (NGT) ($P=0.003$) such that with each decade it decreased 11% (~1.1% per year). No significant correlation with age was found in the IGT group ($P=0.53$). First-phase insulin release was negatively correlated with age in both groups (all $P<0.05$) with the index for first- and second-phase insulin release decreased similarly at a rate of approximately 0.7% per year in people with NGT. In people with IGT, the disposition indexes for first- and second-phase insulin release decreased at greater rates (approximately 2.2 and 1.4% per year, $P=0.002$ and 0.009 , respectively, vs. NGT), with the decrease in first phase being greater than that of second phase ($P=0.025$). Second-phase insulin release did not change with age in either group [78]. Therefore, it likely the combination of both decreased insulin secretion and insulin resistance that leads to glucose intolerance with advanced age.

Colon

Despite the abundance of data suggesting that colonic transit time is not decreased in the elderly, constipation, defined as fewer than three bowel movements per week [79], continues to be one of the most common chronic digestive complaints in this population [80]. About 9–34% of men and women over

age 65 suffer from constipation compared to 4% of the younger population and 19% of the middle-aged population. The cause of constipation is typically ascribed to a low-fiber diet, sedentary lifestyle, and colonic motility disturbances [21] (Table 58.4). Of course, routine screening for colon cancer, including serial stool guaiac tests, flexible endoscopy, or barium enema, is mandatory for the workup of new constipation.

There is a high rate of laxative use in the elderly (reported in 32% of nursing home patients). Constipation in the elderly may produce serious complications, such as acute mental confusion, urinary retention, urinary incontinence, fecal impaction, stercoral ulceration, and even bowel perforation. The primary symptom older people use to describe their constipation is the feeling

of having to strain excessively to defecate. This may be due to outlet delay caused by pelvic dyssynergia, which is a paradoxical increase in anal canal pressure during attempts to defecate. This was found to be the predominant mechanism for constipation in ten of ten otherwise healthy patients over 65 in a study done by Cheskin et al. Colonic inertia, or total gut transit time over 67 h, was found in two of these patients, and rectosigmoid contractions in response to balloon distention was seen in only one subject [81].

The reasons for constipation in the elderly are multifactorial, resulting from decreased muscle tone and motor function of the colon causing decreased propulsive action. Madsen and Graff [32] studied gut motility and found that normal aging decreased colonic motility (age 74–85). Another possibility is a decrease in the neuron density in the myenteric plexus. Gomez et al. found that there was a 37% decrease in the number of neurons in the myenteric plexus in six colon specimens from elderly patients (average age 77.7 ± 7.6 years) with no previous digestive pathology [80]. Similarly, Koch et al. found a significant decrease in inhibitory junction potential in human colon with age, an association noted with other functional obstructions, as in Hirschsprung's disease [82]. This reduced propagation velocity likely explains the decreased rectal compliance often seen in elderly patients with constipation. A noncompliant rectum would be consistent with an infrequent urge to defecate, presence of stools in the rectum for a prolonged period of time, and finally, the straining often resulting in the passage of hard, pellet-like stools [83].

Constipation is also a side effect of many drugs commonly used in the elderly. In a study of 800 nursing homes, residents (age 65–105, mean 84.5 years) who were receiving psychoactive medication. Monane et al. evaluated the relation of these drugs to constipation based on reported frequency of laxative use. The investigators found that laxative use was significantly higher in residents taking highly anticholinergic antidepressants such as amitriptyline (odds ratio 3.12), diphenhydramine (odds ratio 2.18), or highly anticholinergic neuroleptics such as thioridazine (odds ratio 2.01); it was also high in the very old (age ≥ 85) (odds ratio 2.23). Among the factors that did not show a correlation with increased laxative use were gender, decreased functional status, impaired cognitive function, and the use of benzodiazepines or antiparkinsonian agents [84].

Anorectum

Anorectal physiology plays a major role in the function of large bowel and in pelvic disorders [85]. The increase in fecal incontinence and constipation seen during old age is sometimes caused by mechanical changes in the rectum known as pelvic outlet obstruction [86]. Anal incontinence is seen

TABLE 58.4 Causes of constipation

Primary		
Increased colonic mass movement of unknown etiology

Source: Data from Cheskin [98]

predominantly in women, increases with advancing age, and is due to insufficient anal sphincter function. In a study of 61 healthy women with a mean age of 44 (age range 20–90), the anal pressure was recorded along with rectal compliance and sensation, through use of manometry, balloon distention, and a visual analog scale, respectively. Anal sphincter appearance and pelvic floor motion also were assessed by static and dynamic magnetic resonance imaging, respectively, in 38 of 61 females. Age-related changes were found along the length of the anal canal where the rectal compliance, anal resting and squeeze pressures, rectal compliance, rectal sensation, and perineal laxity were all reduced in older subjects [87].

In another study that explored the relationship between age and anorectal function, McHugh and Diamant [88] measured the resting anal canal pressures (RAP) and maximal squeeze pressures (MSP) of 143 incontinent patients and a control group of 157 healthy patients (aged 20–89). In healthy men and women age 40 and older, there was a decrease in RAP and MSP (women > men). For women, parity did not correlate with RAP or MSP. In the group with fecal incontinence (FI), 39% of females and 44% of males fell within the “normal” range for both the RAP and MSP. For all patients with FI, 41 and 17% had impairment of one or both parameters, respectively. As you can see, defining appropriate anorectal functioning is difficult, as a good deal of fecally incontinent men and women fell into the “normal” range.

Parity, however, may be associated with rectal prolapse that has a higher incidence in women and the elderly and is thought to be related to pelvic floor disease. In this condition, the rectum bulges into the perineum, tightening the puborectalis, and increasing anorectal angulation. The pudendal nerve is stretched as the rectum herniated through the weakened anal sphincter [89].

Anorectal physiology can also be evaluated in terms of recovery of function after an operative procedure. Young and elderly patients who have undergone an ileoanal reservoir procedure following a colectomy and ulcerative colitis or familial polyposis have been compared [90]. These patients were evaluated pre- and postoperatively with manometry for anorectal pressures and clinical outcomes by a questionnaire. No difference in preoperative anorectal pressures or in clinical outcome was found between the two groups. Also, despite the transient impairment of internal anal sphincter function seen in these patients, there is complete recovery after ileostomy closure.

Colorectal Cancer

The incidence of many types of neoplasia increases as humans age. The proliferative potential of the gastrointestinal tract, which turns over its entire epithelium every 24–72 h, makes it particularly susceptible to neoplasia [44].

The mean age of presentation is 71, and two-thirds of the 150,000 new cases of colon cancer each year occur in patients over age 65 [91].

Repeated and prolonged insults from environmental factors such as chemicals and radiation are external influences that affect genetic stability. Colon cancer is associated with genetic abnormalities such as mutations and, more commonly, deletions of tumor suppressor genes. Genomic entropy has been shown to increase with time, making genetic instability (and therefore the malfunction of genetic mechanisms such as DNA repair) more common in the elderly [92]. Even the pathology of aging itself may eventually give way to carcinogenesis.

Colorectal carcinomas appear to arise from adenomas, and the idea that carcinogenesis evolves in a multistage process is generally accepted [91]. It is described as a series of genetic alterations resulting in progressive derangement of the genetic factors that control normal growth. Vogelstein et al. looked at four genetic alterations in 172 colorectal tumor specimens representing various stages of neoplastic development: *ras* gene mutations and allelic deletions of chromosomes 5, 17, and 18. Specimens consisted of 40 predominantly early stage adenomas from seven patients with familial adenomatous polyposis (FAP), 40 adenomas (19 without associated foci of carcinoma and 21 with such foci) from 33 patients without FAP, and 92 carcinomas resected from 89 patients. The *ras* gene mutations were found to have occurred in a significantly higher proportion of adenomas >1 cm and in carcinomas (58 and 47%, respectively) than in adenomas <1 cm in size (9%). Sequences on chromosome 5 that are linked to the gene for FAP were present in adenomas from patients with polyposis but were lost in 29 and 35% of adenomas and carcinomas, respectively, from other patients. Carcinomas and advanced adenomas showed a higher rate of deletion of a specific region of chromosome 18 (73 and 47%, respectively) than in earlier-stage adenomas (11–13%). Chromosome 17p sequences were usually lost only in carcinomas (75%). The clinical progression of the tumors developed synchronously with these four genetic alterations. These findings are consistent with the model of tumorigenesis in which the development of cancer occurs in stepwise fashion, involving the mutational activation of an oncogene together with the loss of genes responsible for tumor suppression [93].

In addition to the higher incidence in the elderly, colon cancer also has been shown to have characteristically different locations of occurrence. In a review of 222 patients with colon cancer over age 60, Schub and Steinheber found that there was a higher incidence of right-sided lesions and a decreased incidence of rectosigmoid lesions as the population aged. For patients in their sixth decade, 8% of the tumors were located in the right colon, 9% in the transverse colon, 6% in the descending colon, and 77% in the rectosigmoid. During the seventh decade, 22% were located in the right

colon, 11% in the transverse colon, and 58% in the rectosigmoid area. In the oldest group (older than 80 years) 29% were in the right colon, 14% in the transverse colon, 9% in the descending colon, and 49% in the rectosigmoid area. This trend was found to be statistically significant by chi-square analysis ($P < 0.05$). This “rightward” shift was also associated with a trend toward more favorable staging. The authors believed that it reflects an increase in the proportion of elderly patients with cancer and a predilection toward right-sided lesions with aging [94].

Similarly, Toyoda et al. did a retrospective study using patients from the Osaka Cancer Registry between 1974 and 2003 and found an increased incidence of proximal colon cancer in the elderly (from 22.5 to 34.6% among men and from 25.0 to 46.8% among women for age ≥ 80) over that time period. Among women, right colon cancer was more common in the elderly than in the young [95].

Conclusions

As technology and medical innovation continues to evolve, we will reap the benefits of longevity, and it is clear that our population reflects that the elderly promise to be one of its fastest growing segments. Despite these benefits, issues related to aging can often hinder one’s quality of life and often times lack a definitive solution. The scientific explanation of these events eludes us, as for the most part there are no real differences in histology, motility, or mucosal structure. With continued study of aging as it relates to the gastrointestinal epithelial cell we can yield additional information on incidence of gastrointestinal malignancies. A better understanding of the factors related to aging will help us to improve the diagnosis and treatment of gastrointestinal ailments. The diagnosis and treatment of ailments in other organ systems are addressed in the chapters that follow.

Chapter 59

Benign Esophageal Diseases in the Elderly

Prathima Kanumuri and Neal E. Seymour

Introduction

Noncancer conditions of the esophagus and esophagogastric region may have implications in elderly patients that differ from those encountered in younger age groups. Special consideration must be given to the unique presentations as well as to the physiologic impact of treatments and treatment complications in this vulnerable population. Minimally invasive approaches are now preferred for most esophageal diseases that require surgical treatment. Despite these and other improvements in therapy, benign esophageal disorders continue to present great challenges to practitioners treating the geriatric population.

Gastroesophageal Reflux Disease

The full spectrum of gastroesophageal reflux disease (GERD) symptoms and complications are observed in elderly patients and present specific management considerations. Although GERD does not itself present a significant risk for mortality in the elderly, it may impair quality of life and lead to considerable complication-related morbidity. Patient tolerance of severe symptoms is often poor, and complications such as chronic upper aerodigestive manifestations, esophagitis with ulceration, peptic stricture, and Barrett's esophagus may pose significant management challenges in the elderly.

Pathophysiology

The antireflux barrier at the gastroesophageal junction (GEJ) is an anatomically and physiologically complex zone, which consists of (1) the intrinsic lower esophageal sphincter (LES) pressure (10–30 mmHg), (2) intra-abdominal location of the LES (3–4 cm below the diaphragm), (3) extrinsic

compression of LES by the crural diaphragmatic sphincter, (4) integrity of the phrenoesophageal ligament, and (5) maintenance of an acute angle of His. Disruption of the antireflux barrier and abnormal clearance of esophageal contents results in increased exposure of the esophageal lumen to gastric refluxate (acidic or alkaline) [1] (Table 59.1).

Asymptomatic elderly patients differ physiologically from their younger counterparts (Table 59.2) [2–10]. They may have decreased LES pressure, abnormal esophageal motility and clearance, and an increased pain threshold. Older patients may be more likely to take medications that decrease LES tone and potentiate reflux events. These include nitrates, calcium channel blockers, theophylline, benzodiazepines, anticholinergics, and tricyclic antidepressants. Translocation of the esophagogastric junction and LES into the mediastinum through the esophageal hiatus (type 1, sliding hiatal hernia) (Fig. 59.1) occurs more frequently with increasing age [11] and is thought to contribute to pathologic reflux by exposing the LES a decrement in extraluminal pressure in the chest as compared to the abdomen. This relatively lower extraluminal pressure permits LES tone to be more easily overcome by intragastric pressure, leading to reflux. Marco et al. have shown that the degree of reflux symptoms, LES dysfunction, and esophagitis increase with hiatal hernia size [12].

Clinical Presentation

A population-based study in Olmsted County, Minnesota defined the general incidence of GERD symptoms as 19.8% without significant differences with age [13]. Triadafilopoulos and Sharma similarly reported no clear age-related difference in clinical prevalence of GERD above and below age 65 [14]. However, GERD symptom severity may not correlate as well with the severity of pathology in elderly patients. Johnson and Fennerty reported that 34% of patients >70 years old had severe heartburn with a 37% incidence of endoscopically evident severe esophagitis. In contrast, 82% of patients <21 years old with severe heartburn had severe esophagitis only 12% of the time [15]. Furthermore, Collen et al. reported

TABLE 59.1 Pathophysiologic factors contributing to GERD

Increased frequency and duration of transient LES relaxation
Hypotensive LES (0–4 mmHg) leading to free reflux
Disruption of phrenoesophageal ligament and diaphragmatic sphincter (Hiatal hernia)
Shortening of intra-abdominal LES
Decreased clearance of esophageal contents due to loss of primary and secondary esophageal peristalsis
Decrease in rate of salivation and salivary bicarbonate
Decreased gastric emptying and increased intra-gastric pressure

GERD gastroesophageal reflux disease, *LES* lower esophageal sphincter

TABLE 59.2 Physiological changes of the esophagus in the elderly

LED
Decreased LES pressure [2]
Decreased LES length [3]
Increase in gastroesophageal reflux events during the postprandial period from pharyngeal stimulation [3]
Esophageal motility
Aperistalsis without any specific etiology [4]
Absent or decreased secondary peristalsis with esophageal distention [5]
Increased tertiary contractions (multiple, simultaneous, nonperistaltic contractions) [6]
Decreased amplitude and velocity of peristaltic waves [2, 7]
Impaired esophageal clearance [8, 9]
Higher pain threshold with esophageal distention [10]

LES lower esophageal sphincter

FIGURE 59.1 Retroflexed endoscopic view of type I sliding hiatal hernia. The endoscope is seen emerging from the true esophagogastric junction into the hernia above the muscular ring of the hiatus.

that for a given level of severe reflux symptoms, patients >60 years old had more severe esophagitis compared to younger patients [16]. Zhu et al. reported that 21% of patients >65 years with GERD present with endoscopically severe esophagitis, while only 3.4% of patients under 65 years have severe esophagitis [17]. Patients with GERD present with symptoms which can be described as typical or atypical or a combination of both (Table 59.3). Atypical symptoms may be more prevalent in the elderly [13, 18]. Alkaline reflux may also be more frequent and can be associated with respiratory

TABLE 59.3 Symptoms and complications associated with GERD

<i>Typical</i>
Heartburn
Regurgitation
<i>Atypical symptoms</i>
Chest pain
Dysphagia
Dyspepsia
Anorexia, weight loss
Dental problems
<i>Atypical symptoms: Respiratory</i>
Globus sensation
Laryngitis
Hoarseness
Chronic cough
Asthma
Bronchitis
Aspiration pneumonia
Pulmonary fibrosis
<i>Complications</i>
Esophagitis
Gastrointestinal bleeding
Peptic strictures
Barrett's esophagitis

GERD gastroesophageal reflux disease

symptoms more often than with heartburn [19]. Pellegrini et al. found that individuals with alkaline reflux have less heartburn, regurgitation, and dysphagia but at least as much esophagitis and stricture risk as those with acid reflux, as well as a higher frequency of pulmonary symptoms [20].

Long-standing GERD can result in complications which may lead to significant morbidity. The incidence of erosive esophagitis (45.4%), esophageal ulcers (6%), and esophageal strictures (8.4%) all increase with age. Furthermore, patients with esophageal ulcers or strictures are generally older than patients with uncomplicated esophagitis [21]. In one report, esophagitis was the cause of upper gastrointestinal bleeding in 21% of patients >80 years [22].

Barrett's esophagus, or columnar metaplasia, is a marker of severe chronic esophageal mucosal injury and has been reported to occur in as many as 10–12% of patients with GERD [23, 24]. The prevalence of Barrett's esophagus increases with age and plateaus by the seventh decade [25]. It occurs more frequently in patients greater than 60 years of age (34 vs. 12%) [16]. Elderly patients with Barrett's esophagus experience less severe symptoms compared to younger patients, which may lead to delayed recognition of the condition [14]. The outcome of Barrett's esophagus which is of utmost concern is its progression to adenocarcinoma, but there are no compelling data that define this risk in the elderly. In a meta-analysis of 41 Barrett's esophagus surveillance studies, the reported cancer incidence was found to be between 6 and 9 per 1,000 person-years follow-up [26]. The presence of ulcers, strictures, and nodules was associated with increased cancer incidence. Patients who developed cancer had

significantly longer Barrett's segments compared to patients who did not. However, these data did not stratify risk by age, and it is uncertain to what extent age may be an independent risk factor either dysplasia or cancer.

Treatment for Barrett's esophagus is close surveillance, and either medical or surgical control of reflux with the aim to avoid progression of disease. Standard therapy for high-grade dysplasia in Barrett's is esophagectomy. Mucosal ablative therapies (photodynamic therapy, argon plasma coagulation, and cryoablation) for high-grade dysplasia have seen expanded use and could offer benefits to elderly patients, if the morbidity and mortality risk associated with esophagectomy can be avoided. However, uncertain efficacy and potential to undertreat cancer present at the time of the therapy remain a matter of concern.

Diagnostic Studies

Tests to diagnose GERD, GERD complications, and responses to therapy are listed in Table 59.4. GERD symptoms are frequently under treatment with proton pump inhibitors (PPI) or histamine receptor antagonists (HRA) before any diagnostic tests are done. There should be a low threshold to proceed with endoscopy in elderly patients because of the recognized risk of more advanced disease in the face of less severe or atypical symptoms in comparison to younger patients. Endoscopy with biopsy is currently the only study that can effectively identify esophagitis, rule out Barrett's and cancer, as well as document healing of esophagitis

TABLE 59.4 Diagnostic studies for GERD

Test	Purpose of study
Cine esophagram	Evaluate anatomical causes for dysphagia; document presence of hiatal or paraesophageal hernia; rule out achalasia, scleroderma, strictures, diverticuli, webs and masses
Endoscopy	Evaluate endoscopy positive vs. negative reflux disease; documentation of healing esophagitis; rule out complications of GERD (esophagitis, stricture, and BE), peptic ulcer disease and cancer
Esophageal manometry	Evaluate LES function; rule out esophageal dysmotility before proceeding with antireflux surgery
pH monitoring	Document abnormal acid exposure in symptomatic endoscopy negative patients being evaluated for endoscopic or surgical antireflux therapy; evaluation of patients on PPI therapy with persistent typical symptoms; document adequacy of PPI therapy in patients with complications due to GERD
Esophageal impedance testing	Evaluation of endoscopy negative patients with persistent symptoms despite PPI therapy
Bile acid reflux monitoring	Evaluation of patients with persistent reflux symptoms with normalization of distal esophageal acid exposure confirmed by pH studies

GERD gastroesophageal reflux disease, BE Barrett's esophagus, PPI proton pump inhibitor

with therapy. Ciné esophagography can help characterize anatomic and functional features of the esophagus during the passage of ingested barium materials of varying consistencies. Some motility characteristics and disorders (Table 59.4) as well as esophagogastric junction anatomy can be defined with the study, and it can be particularly useful in evaluating dysphagia.

Complex or suspected reflux disease and persistent or atypical symptoms should be further evaluated using more objective tests, especially when antireflux surgery is being considered. 2007 American College of Gastroenterology practice guidelines recommend ambulatory pH monitoring to identify pathologic esophageal acid exposure in endoscopy negative patients being considered for endoscopic or surgical antireflux procedures and patients who are symptomatic on PPI therapy. Symptom correlation index can establish likelihood of causality in the relationship between symptom occurrence and episodes of esophageal acid exposure. Although pH monitoring can also be used to evaluate effectiveness of PPI therapy, a specific threshold value for adequate suppression of esophageal acid exposure has not been defined [27], and no age-specific guidelines for the use of this test are available.

Ambulatory pH monitoring can be performed using a nasopharyngeal catheter system or a wireless pH capsule ("Bravo" probe, Medtronic, Minneapolis, MN) that transmits information to an external receiver. Results from the two systems correlate well, but there may be advantages with wireless pH monitoring. The most important is that the modality is associated with less discomfort, less interference with daily activities, and better patient satisfaction compared to the traditional catheter system. Less interference with daily activities will provide more accurate information about reflux episodes [28]. Furthermore, pH monitoring can be performed for more than 24-h periods, and it may be more feasible to study patients on and off PPI therapy. Disadvantages include the need to place the capsule endoscopically, which adds cost and the potential problems of an invasive procedure. Some patients may have severe chest pain, and the capsule may either dislodge early or not dislodge at all, both of which are problematic situations. Wireless pH monitoring might offer advantages in elderly patients based on improved tolerance, but there are no data that specifically support this assumption.

Esophageal impedance monitoring detects changes in resistance to electrical current across adjacent electrodes with the movement of solids, liquids, and gases. It can detect both acid and alkaline reflux (even very weak patterns of reflux) and evaluate esophageal bolus transit when combined with motility studies. Specific monitoring of bile acid reflux is possible by using a probe that detects bile by spectrophotometry. AGA guidelines suggest that these tests may be useful in patients with reflux symptoms despite PPI therapy and normal pH monitoring studies [27]. They are not widely used at this time because the long-term clinical implications of non-acid reflux are not well studied. It is unclear at this time how recognition of this entity might change management in elderly patients.

Chest pain symptoms in the elderly deserve special mention. The most obvious concern lies in the physician's ability to distinguish cardiac from noncardiac chest pain (NCCP) and to institute the appropriate treatment. Although most patients with GERD-induced chest pain will give a history of antecedent reflux symptoms, the possibility of myocardial ischemia ought to be considered and basic investigations conducted so as not to miss this diagnosis. There is considerable overlap in symptoms that could be attributable to either GERD or pain of cardiac origin. DeMeester et al. performed 24-h pH probe studies in patients with typical angina pectoris symptoms and normal cardiac catheterizations and demonstrated reflux to be present in 46% [29]. A positive correlation between chest pain episodes and acid reflux during the pH probe study can be demonstrated in up to 50% of patients with NCCP [30].

Treatment

Irrespective of patient age, the goals in the treatment of GERD are to ameliorate symptoms, promote healing of esophagitis, maintain remission, and prevent long-term complications. These goals may be achieved using various modalities.

Nonsurgical Treatment

Life style or behavioral modifications can alleviate symptoms in mild reflux disease when employed alone or with medical therapies. These might include the elevation of the head and chest during sleep, avoidance of supine position or sleep less than 3 h after meals, weight loss in overweight patients, smoking cessation, and avoidance of foods associated with reflux (e.g., high fat foods, chocolate, peppermint, coffee, and alcohol). As mentioned previously, selected medications may decrease LES tone. Caution with these as well as with medications that might predispose to pill esophagitis (potassium tablets, iron sulfate, and alendronate) should be exercised.

Histamine receptor antagonists (cimetidine, ranitidine, famotidine, and nizatidine) may be effective but are used less frequently than proton pump inhibitors (PPIs) as first-line therapy. PPIs (omeprazole, lansoprazole, rabeprazole, pantoprazole, and esomeprazole) inhibit the H^+/K^+ ATPase proton pump. They have become the mainstay of medical therapy for significant GERD and are now available over-the-counter (omeprazole). If symptoms are suggestive, empiric treatment is usually started before diagnostic tests are done, and prompt clinical improvement is generally taken as confirmatory of the GERD diagnosis. Historical exceptions to prompt use of PPIs rather than investigations include long-standing GERD and alarm symptoms such as anemia, weight loss, and dysphagia [31]. Since elderly patients may present with more advanced disease and less severe symptoms, an argument can be made for the use of endoscopy prior to starting prolonged acid suppression in order to clearly establish the presence of esophagitis.

Almost 50% of patients with GERD suffer frequent relapses and need some form of maintenance therapy. PPIs are currently regarded as the most effective medications available for acute as well as maintenance therapy for GERD [32], although H_2 receptor antagonists may also be effective if PPI treatment cannot be given. Since PPIs are long-acting medications, dosing is convenient for older patients. Added potential advantages include easy administration in older patients with swallowing problems (granules can be mixed in soft food or liquids) and the fact that dose adjustments are not necessary in hepatic and renal insufficiency [33]. Some studies have shown an increased risk for respiratory infections, Clostridium difficile colitis, and osteoporosis with PPI use [34].

Cisapride is a prokinetic agent which may be available for use in GERD outside the USA, having been removed from the US market in 2000 due to increased risk for cardiac arrhythmias. Metoclopramide can be problematic in elderly patients due to CNS side effects (sedation and tardive dyskinesia). Other promotility drugs such as Tegaserod (serotonin agonist) and Baclofen (GABA agonist) may have some efficacy in GERD but are not standard therapies.

Surgical Treatment

Indications for surgical treatment of GERD include (1) patient choice in order to discontinue medical therapy, (2) intolerance of medical therapy, (3) persistence of symptoms on medical therapy, and (4) complications of GERD including persistent esophagitis on medication, peptic strictures, and Barrett's esophagus (although the latter indication may be controversial). The goals of surgery are to repair any associated hiatal hernia, establish an intra-abdominal length of esophagus, and perform a fundoplication as a barrier to reflux. Nissen or 360° fundoplication (Fig. 59.2) is the most frequently performed

FIGURE 59.2 Laparoscopic Nissen fundoplication. The loose nature of this complete (360°) wrap of gastric fundus around the esophago-gastric junction and distal esophagus is demonstrated by the insertion of an instrument below the left-sided fundic component of the wrap.

antireflux procedure. Toupet or 270° fundoplication has generally been reserved for GERD patients with ineffective esophageal motility, although its efficacy as compared to a loose Nissen fundoplication is controversial [35, 36]. There are numerous other types of antireflux procedure intended for use via transabdominal or transthoracic access methods, but a full discussion of surgical antireflux treatments is beyond the scope of this chapter. It can currently be stated that laparoscopic antireflux procedures represent the surgical standard of care for GERD, and advantages relative to open procedures are well established [37]. Investigations of surgical treatment of GERD in the elderly have generally shown that outcomes are favorable. Table 59.5 summarizes eight studies that compare surgical outcomes in “older” (>60 years) and “younger” patients (<60 years of age) [38–45]. These have established that postoperative symptom relief is not adversely affected by advancing age with mean follow-up of between 3 months and 5 years. There may be a perception that postoperative complication rates are higher and length of hospital stay are greater for patients >60 years of age, but this has not been consistently observed for antireflux surgery. Although patients >60 years had significantly higher American Society of Anesthesia (ASA) score in four studies and a higher rate of comorbidities in one study, this did not closely correlate with an increase in complication rate and length of stay. The likelihood of mortality with antireflux surgery is very close to zero in both populations.

Current data suggest that antireflux surgery can improve formally measured quality of life in elderly patients. Kamolz et al. reported the use of the gastrointestinal quality of life index (GIQLI) to assess postoperative outcomes in 72 patients greater than 65 years of age. Scores were significantly improved 3 months after surgery compared to preoperative values. This improvement persisted 1 and 3 years after surgery and was similar to scores in healthy individuals [46]. Fernando et al. [41] and Wang et al. [45] showed that SF 36 health survey and GIQLI assessments of global and disease-associated quality of life postsurgical outcomes were not significantly different in patients <60 years and >60 years of age. The overwhelming weight of evidence indicates that antireflux surgery is both effective and safe in the elderly, and that outcomes are comparable to those achieved in younger patients.

Intraoperative complications of antireflux surgery are uncommon. Esophageal perforation is rare and may result from dissection or bougie injuries. Common causes of intraoperative bleeding are adhesiolysis, or injury to the left lobe of liver or the spleen. Bleeding is generally controlled by local measures and rarely requires conversion to an open procedure. Splenic injuries and splenectomy, which were surprisingly common events with open fundoplication (2–5%), are rare occurrences in laparoscopic antireflux surgery. Pneumothorax is also rare and is thought to be due to extensive dissection into the mediastinum. Chest tube placement is rarely required due to the rapid uptake of CO₂. Conversion rates from laparoscopic to open procedures are less than 5%.

Coelho et al. evaluated complications of laparoscopic fundoplication in 77 patients >70 years of age and reported 7.8% gas bloat syndrome, 5.2% dysphagia, and 2.6% gastric ulceration incidences [47]. Although most dysphagia after fundoplication either resolves or responds well to modest dietary measures, severe dysphagia symptoms may on rare occasions require endoscopic dilatation or surgical revision of fundoplication. Technical considerations that minimize the likelihood of postoperative dysphagia include routine division of the gastrosplenic ligament and short-gastric vessels, and adequate fundic mobilization for a loose wrap. The incidence of anatomic failure of antireflux procedures ranges from 3 to 6%. These cases include fundoplication disruption or slipping, or axial herniation of the fundoplication into the mediastinum. Pledged suture repair of the hiatus and reinforcement of the defect with a mesh may decrease incidence of some types of anatomic failure [48].

Endoscopic Treatment

Endoscopic therapy for GERD has shown to significantly decrease PPI use, improve symptoms, and decrease but never normalize acid exposure in patients with mild forms of GERD. Proposed exclusion criteria include hiatal hernias greater than 2 cm, esophagitis greater than grade II, and disease refractory to PPI therapy [49]. Currently there are three FDA approved devices available for GERD endoluminal therapy: (1) EndoCinch (Bard, Davol, Inc., Cranston, RI),

TABLE 59.5 Laparoscopic antireflux surgery outcomes in elderly (>60 years) vs. adult (<60 years) patients

PARAESOPHAGEAL HERNIA

Case Study: Part 1

Presentation: An 81-year-old man with mild dementia, hypertension, and atrial fibrillation cared for at home by his 74-year-old spouse was brought to the emergency department with a 12 h history of vomiting and chest pain. He was accompanied by his wife, who provided most of the health history information. He had significant short-term memory loss, but walked for exercise and enjoyed fishing and watching televised baseball games. The patient's knowledge of recent events was very incomplete, although he answered question appropriately and was oriented to time and place. His wife reported that he had had recent difficulties with tolerance of certain ingested foods and beverages. Over the past 2 months, he had increasingly frequent interruption of meals with agitation and "spitting up" small amounts of undigested food. He complained of substernal chest discomfort with some of these episodes but was unable to provide more specific information on this symptom. He had been able to take his oral medications until the present episode. At presentation, the patient was comfortable, but had not eaten and had only taken in minimal fluids over the previous 12 h. Three weeks prior to presentation, in investigation of his symptoms, he had a 12-lead EKG that showed his usual rate-controlled atrial fibrillation and a radionuclide cardiac perfusion scan was normal. He also had a chest X-ray that showed an air–fluid level suspected to be stomach occupying the lower half of the left lung field. His medications included warfarin, hydrochlorothiazide, and lisinopril. He had no abdominal surgery history, but had bilateral knee replacements 12 years previously. The remainder of his review of systems was negative, with the exception of knee and back pain for which he took acetaminophen.

Physical examination: The patient was a pleasant, Caucasian man of medium build. He had irregular heart

rhythm with a rate of 75 bpm and BP 147/85. Breath sounds were present, but when he rocked front-to-back, a splashing sound was auscultated at the left lung base. His abdomen was soft and nontender. The remainder of his examination was unremarkable. Diagnostic studies: Serum electrolytes, BUN, and creatinine were normal. His automated WBC count was 7,200 with 68% leukocytes, and his hematocrit was 38%. INR is 1.9. His chest X-ray was available for review, and based on suspicion of the presence of a paraesophageal hernia, an immediate barium esophagram was obtained (Fig. 59.3), which identified a Type III paraesophageal hernia.

FIGURE 59.3 Barium esophagram of a type III (paraesophageal) hiatal hernia. In this case, there is clear demonstration of the relationship between the axially rotated gastric fundus and the adjacent esophagus, which tapers at the expected location of the diaphragmatic hiatus.

(2) Plicator (NDO surgical, Inc., Mansfield, MA), and (3) Stretta (Curon Medical, Inc., Fremont, CA). The principles by which these devices operate are (1) Plication of the submucosa at the GEJ (EndoCinch). (2) Full-thickness serosa-to-serosa plication at the GEJ (Plicator). (3) Radiofrequency thermal therapy delivered to LES (Stretta). Potential advantages in elderly patients include performance with conscious sedation, and relatively short-procedure duration. There may be applications in poor surgical candidates or as a bridge

between medical and surgical therapy. However, based on current literature, there are no clear indications based on perceived or measured superiority relative to traditional surgical measures. Published studies have been small and more focused on safety and feasibility than on long-term durability and efficacy. With increasing experience, evolving techniques and hardware, as well as more thorough investigation, endoluminal therapies may become a viable option in the treatment of GERD, with specific applications in the elderly.

FIGURE 59.4 Laparoscopic view of a type III (paraesophageal) hiatal hernia, with the herniated body and fundus of the stomach above the right crural pillar.

Paraesophageal hernia is primarily a disease of the elderly and the average age of diagnosis is 60–70 years. The true incidence of hiatal hernias is difficult to determine because majority of patients remain asymptomatic and therefore undiagnosed. There are four types of hiatal hernias. (1) Type I (Sliding hiatal hernia): Esophagogastric junction migrates through the hiatus and is commonly associated with GERD. (2) Type II: Gastric fundus herniates through the hiatus with esophagogastric junction in an intra-abdominal position. This is a true paraesophageal hernia. (3) Type III (combination of Type I and II). In this hernia type, gastric fundus and esophagogastric junction herniate into the mediastinum (Fig. 59.4). (4) Type IV: Type III hernia with herniation of other viscera such as spleen or colon [50]. Type II, III, and IV hiatal hernias are called paraesophageal hernias, and Type III hernia is the most common among them (90%). Type I or sliding hiatal hernias are at least seven times more common than paraesophageal hernias [51].

Pathophysiology

Paraesophageal hernias occur more frequently with advancing age and are believed to result from progression of a sliding hiatal hernia. Prolonged repetitive stretching of the phrenoesophageal membrane due to movement of the esophagus during swallowing, as well as increased intra-abdominal pressure due to conditions such as morbid obesity, COPD, asthma and chronic constipation, may contribute to more complex patterns of gastric herniation into the chest [51].

Clinical Presentation

Symptoms associated with paraesophageal hernias are primarily related to partial or complete gastric obstruction. Patients present with nausea, bloating, early satiety, chest pain, and fullness relieved with vomiting and dysphagia. Fifteen to thirty percent of patients with paraesophageal hernias complain of GERD symptoms [52, 53]. Patients with larger hernias may suffer from chest pain and shortness of breath. Paraesophageal hernias may be associated with chronic blood loss and anemia due to gastric erosions from prolonged trauma [54]. Gastric volvulus is a possible complication of paraesophageal hernias, with rotation either along the long axis of the stomach (organoaxial) or along a perpendicular axis (mesenteroaxial). Patients with completed volvulus can present emergently with acute gastric obstruction and potentially with gastric strangulation. Symptoms associated with this presentation are epigastric pain, persistent retching and vomiting, bloody vomitus due to gastric ischemia and ulceration, and an acute abdomen and sepsis, if a gastric perforation has occurred. Previous studies have reported an acute presentation in 29% of patients with paraesophageal hernias [55, 56]. However, a recent study by Stylopoulos et al. looked at five studies and estimated the probability of developing acute symptoms to be 1.16% per year. The lifetime risk for developing acute symptoms is 18% for 65 years and decreases as patient's age increases [57]. Arguments for mandatory surgical treatment of paraesophageal hernia are generally based on the need to avoid this variably estimated risk, which may be favorably affected by advancing patient age.

Diagnostic Studies

Chest radiograph may demonstrate an air–fluid level in the left chest. Upper gastrointestinal contrast study with barium is the study of choice to diagnose paraesophageal hernias (Fig. 59.3). Computed tomography can also establish the diagnosis (Fig. 59.5). Upper endoscopy can aid in recognition of a paraesophageal component of a hiatal hernia and will provide other information such as the presence of esophagitis or ulcerations. Twenty-four hours pH monitoring and esophageal manometry can be considered in patients with GERD symptoms, but may not influence surgical planning.

Treatment

Surgical management of symptomatic and asymptomatic paraesophageal hernias has historically represented a mandatory standard of care. This is based largely on reports of a

FIGURE 59.5 CT chest coronal section of a type III hiatal hernia (paraesophageal), with adjacent contrast-filled esophagus between the distended, herniated stomach, and the thoracic vertebrae. Such studies have become increasingly valuable in more precisely defining anatomic relationships in complex hernias of this type. This information can be used to better understand the condition, or as an aid in operative planning.

high (28–30%) incidence of acute symptoms necessitating emergency operations, which were associated with high rates of morbidity and mortality [55, 56]. Surgery continues to be the treatment of choice for symptomatic paraesophageal hernias. However, the treatment of asymptomatic and minimally symptomatic hernias has become more controversial. Allen et al. followed 23 patients managed nonoperatively for an average of 78 months and reported that only four developed progression of symptoms and that the two patients who underwent elective repair did well [52]. Stylopoulos et al. assessed outcomes of elective laparoscopic hernia repair vs. watchful observation in patients with asymptomatic and minimally symptomatic indications based on information from 20 published studies. Using a predictive model, it was determined that less than one in five 65-year-old patients and only one in ten 85-year-old patients will benefit from elective surgical treatment [57].

The goals of operative treatment of paraesophageal hernias are (1) reduction of the herniated stomach (or other viscera), (2) reduction and excision of the hernia sac, (3) hiatal hernia repair with or without prosthetic mesh, and (4) secure subdiaphragmatic positioning of the stomach. Although the use of fundoplication in paraesophageal hernia repair remains controversial, it is frequently used on the assumption that it may reduce recurrent hernia risk as well as reduce

postoperative GERD occurrence. As many as 60% of patients with type III hernias have diminished LES pressures and abnormal esophageal pH monitoring studies [59]. Willekes et al. reported that as many as 30% of patients had preoperative reflux symptoms and that some patients develop postoperative reflux despite the absence of preoperative reflux symptoms. He concluded that GEJ and LES physiology cannot be predicted once it has been surgically disturbed and all phrenoesophageal supporting attachments are divided [53]. Despite these observations, there are no compelling data to support either the use or omission of fundoplication in this clinical situation, and no specific data in elderly patients to guide this decision.

Minimally invasive surgery has become the preferred method of management for paraesophageal hernias, with the well-founded expectation of decreased postoperative pain, length of stay, and morbidity and mortality compared to open surgical methods [59–62]. A recent large series (203 patients) of laparoscopic repair for giant paraesophageal hernia (1/3 or more of stomach herniation into chest) suggests a pattern of disease skewed toward more elderly patients. The mean patient age was 67 years (34–91 years) and median follow-up was 18 months. The median length of hospital stay was 3 days, morbidity was 28%, and mortality was 0.5. Postoperative symptom relief was excellent to good in 92% of patients [61].

Bammer et al. and Grotentuis et al. evaluated outcomes of laparoscopic paraesophageal hernia repair in patients >80 years of age and >70 years of age, respectively. Results were comparable to studies with mixed age groups [63, 64]. Gangopadhyay et al. compared results of laparoscopic paraesophageal hernia repair in three age groups <65 years (Group 1), 65–74 years (Group 2), and >74 years (Group 3). Group 3 had significantly higher ASA scores and hospital length of stay but their postoperative complication rate, symptom relief, and recurrence rates were comparable to other groups [65]. In a retrospective review of 1,005 patients (>80 years of age) who underwent diaphragmatic hernia repair, 43% of procedures were emergent. Emergency operations were more common among older patients, and the concurrent finding of CHF and was associated with longer hospital length of stay and mortality (14 ± 1 days and 16%) compared to patients who underwent elective repair (7 ± 1 days and 2.5%) [66]. Laparoscopic paraesophageal hernia repair is a safe and effective option in the elderly and they should not be denied surgery based on age alone, because emergency surgery in this population is associated with significant mortality. In elderly and debilitated patients with multiple comorbidities, one should consider shorter, less invasive techniques such as anterior gastropexy or placement of percutaneous endoscopic gastrostomy after the reduction of paraesophageal hernias. Agwunobi et al. and Kercher et al. performed these techniques in small series of high-risk patients (13 and 11 patients) with minimal complications and low recurrence rates [67, 68].

CASE STUDY: PART 2

Treatment plan: The patient was admitted to the Surgical Service and maintenance intravenous fluids were started. Although there was discussion of placement of a nasogastric tube, this was not done as the patient was comfortable and there were deemed to be risks associated with any attempt to position this tube given potential obstructive pathology associated with the hernia. A Geriatric Medicine consult was obtained, and it was decided to observe the patient on a telemetry unit and not to give any of his home medications. If he became tachycardic, this would be treated with intravenous beta-blockers. The decision was made to hold anticoagulation and to give Vitamin K 10 mg and 2 U fresh frozen plasma in anticipation of surgical intervention. On the second hospital day, the patient underwent successful laparoscopic repair of a large paraesophageal hernia, with pledgeted repair of the esophageal hiatus, and Toupet fundoplication. Postoperative care: In the postanesthesia care unit (PACU), he developed rapid atrial fibrillation (130 bpm) with a blood pressure of 105/60. There was no evidence of acute bleeding, and operative blood loss was minimal. He was given two 2 mg doses of intravenous morphine sulfate and three 5 mg doses of intravenous Metoprolol over a 2-h period, and better rate control was achieved, with increase in BP to 135/80. Troponin, CPK, and CPK-MB levels were nonelevated, and a 12-lead EKG showed no change from a preoperative study. After discharge from PACU, he returned to the telemetry unit. On postoperative day #1,

he started a clear liquid diet along with his home medications, including Warfarin. He remained in atrial fibrillation at 70 bpm and telemetry was discontinued. On postoperative day #2, a soft diet was started, which the patient tolerated well. He ambulated well with assistance and was discharged home to follow-up with his surgeon and primary care physician in 1–2 weeks.

Salient Points

1. Although nasogastric tube placement is not absolutely contraindicated in paraesophageal hernia, risk of perforation in this setting should temper use, and placement may be best deferred until operative visualization of the reduced stomach can be achieved. There is no indication for postoperative use of a nasogastric tube after laparoscopic paraesophageal hernia repair.
2. Despite advanced age, repair a paraesophageal hernia ought to be with the expectation of a good postoperative result, although special precautions with comorbidities is required. In a highly symptomatic patient, prompt surgical treatment is suggested to avoid obstructive issues or more dire complications such as completed volvulus with strangulation.
3. A succussion splash, described in the examination findings, can be found in some patients with a large hiatal hernia, but does not identify hernia type, or necessarily suggest the need for intervention.

Esophageal Motility Disorders

Esophageal motility may undergo various physiological changes with aging. Among these are decreased secondary esophageal peristalsis, increased ineffective tertiary contractions, and diminished velocity and amplitude of peristaltic waves (Table 59.2). Esophageal dysmotility may be primary, such as in achalasia, diffuse esophageal spasm (DES) and nutcracker esophagus or secondary to conditions such as systemic sclerosis, polymyositis and diabetes mellitus [69].

Achalasia

Achalasia has two incidence peaks: The first between ages 20 and 40 and the second in more elderly patients. Sonnenberg et al. reported an average age of 78 years for patients with

achalasia based on hospital admission codes, with a steady increase in hospitalization rates between the ages of 65 and 94 years [70].

Pathophysiology

Achalasia is a primary functional disorder of the esophagus characterized by the absence of peristalsis and incomplete relaxation of the LES during swallowing. These characteristics contribute to a functional obstruction at the GEJ [71]. Although occasional familial clustering of achalasia cases has been reported, most are sporadic and of uncertain etiology [72]. The esophageal manifestations of Chaga's disease (*Tripanisoma Cruzi*), which is endemic in South America, can be considered a form of achalasia, but is accompanied by a host of other infection-related problems. It can be observed

in elderly patients and presents particular management challenges largely due to the broader range of systems affected and overall poorer prognosis.

Viral infection has been proposed as a causative factor in achalasia [73, 74]. Reported histologic characteristics are based on resected and autopsy esophageal specimens, and most likely reflect advanced disease findings. Wallerian degenerative changes, loss of myenteric ganglion cells, microscopic degeneration of the vagus nerve, and hypertrophy of the muscularis propria of the distal esophagus have been described [75]. A loss of nitric oxide and vasoactive intestinal peptide (VIP)-containing postganglionic inhibitory neurons in the myenteric plexus may be responsible for impairment of LES relaxation due to unopposed cholinergic stimulation [76–78]. Goin et al. have suggested an autoimmune etiology based on the identification of circulating anti-muscarinic antibodies in chagasic achalasia [79]. The presence of Lewy bodies in the myenteric plexus and loss of neurons in the dorsal motor nucleus of the vagus in both achalasia and Parkinson's disease suggests a possible link between the two diseases, which appear with high prevalence in the elderly.

Aperistalsis in achalasia is not clearly understood. Inhibitory innervation is believed to be critical to the phasic sequence of esophageal muscular contractions and it is possible that loss of inhibitory neurons abolishes peristaltic motor function. Long-term aperistalsis and functional GEJ obstruction can eventually result in a massively dilated and tortuous esophagus devoid of any discernible motor function [71].

Clinical Presentation

The most common symptoms of achalasia are dysphagia to solid food, regurgitation of esophageal contents, weight loss, and various patterns of chest pain. Dysphagia is progressive in achalasia and may also interfere with ingestion of liquids. Other clinical complaints may include cervical level dysphagia and difficulty belching. It has been suggested that some symptoms are related to impaired upper esophageal sphincter relaxation [80, 81].

Dysphagia and impaired esophageal emptying in achalasia is due to both impaired LES relaxation and loss of esophageal peristalsis. There is stasis of varying amounts of undigested food proximal to the LES depending on the capacitance of the dilated esophagus and the rate and quantity of food intake. Patients develop techniques to facilitate esophageal emptying, including slow, purposeful swallowing, avoidance of firm foods, postural changes (twisting, stretching), and ingestion of warm liquids with meals. Approximately 40% of patients have chest pain in the xiphoid or substernal areas, which often prompts evaluation

for cardiac problems. This pain may be increased by exercise and relieved by rest [82]. Achalasia patients also commonly describe "heartburn," which is most likely related to esophageal stasis [83]. Clouse et al. compared clinical presentations of achalasia in patients greater and lesser than 70 years of age. Although symptom patterns were similar in the two groups, fewer of the older patients complained of chest pain [84].

Patients with achalasia are at risk for developing chronic inflammation, ulceration, perforation, and fistulas as a result of chronic stasis and retention. It has been shown that there is a 33-fold increased risk of esophageal carcinoma in these patients, with a yearly incidence of 3.4/1,000. The patients at highest risk are elderly patients with a long-standing history of dysphagia and a markedly dilated esophagus [85].

Diagnosis

A plain chest radiograph may demonstrate a widened mediastinum and an air–fluid level in the posterior mediastinum due to esophageal dilation. A barium esophogram effectively demonstrates the gross esophageal changes, which can include dilation, tortuosity, retention of food and barium, and a symmetric smooth tapering of the esophagus resembling a bird's beak (Fig. 59.6). The most striking gross feature of achalasia is massive esophageal dilation known as sigmoid esophagus or megaesophagus seen in advanced cases (Fig. 59.7).

Upper endoscopy should be considered a mandatory study to exclude peptic stricture and malignancy. The latter condition may be associated with clinical changes similar to those of achalasia, particularly in patients over 60 years of age [86, 87]. A diagnosis of pseudoachalasia can be firmly established only by biopsy and histologic demonstration of carcinoma.

Of all currently available studies, esophageal manometry establishes the diagnosis of achalasia most effectively. Although the resting LES pressure is normal in 40% of patients, up to 80% have absent or incomplete LES relaxation with wet swallows. It must be emphasized that the presence of LES relaxation does not exclude achalasia. Postdeglutitive relaxations may appear complete but usually are of short duration [88, 89]. Loss of normal esophageal body peristalsis is manifested by simultaneous contractions following wet swallows. Contractile amplitudes are low (10–40 mmHg) with frequent prolonged and repetitive waves. Studies have shown increased basal LES pressure in older patients with achalasia compared to younger patients [90, 91]. Chuah et al. demonstrated a linear correlation between age and LES basal pressure in achalasia patients [91].

FIGURE 59.6 Bird's beak deformity of the distal esophagus in a patient with achalasia seen on a barium esophagram. This characteristic appearance in a patient with the clinical features of achalasia is strongly suggestive of this condition.

FIGURE 59.7 Barium esophagram of a megaesophagus in a patient with advanced achalasia. The barium column may be diluted by retained fluid and food in the enlarged and sometimes tortuous esophagus.

Vigorous achalasia is a variant of achalasia characterized by high amplitude (>60 mmHg) simultaneous esophageal contractions, which may be associated with intense chest pain. This form of achalasia may be less frequent in elderly patients.

Treatment

Treatment of achalasia is primarily palliative and is geared towards adequate symptom relief from functional LES obstruction [71]. Variety of nonsurgical and surgical options are available.

Nonsurgical Treatment

Calcium channel blockers and nitrates are the most commonly used pharmacological agents in the treatment of achalasia. Clinical improvement with both sublingual isosorbide dinitrate and nifedipine treatment has been reported; however, symptom relief is variable 53–87% and 0–75%, respectively [92, 93]. These agents must be taken sublingually immediately prior to meals to achieve the desired result. The major potential side effects that might limit this treatment are headache, hypotension, and tachyphylaxis. However, oral pharmacotherapy has not gained popularity because of its short-lived effects, poor symptom relief, and decreasing efficacy with time. They are definitely an option in patients awaiting definitive therapy and the elderly who have failed botulinum toxin therapy and are poor candidates for pneumatic dilatation and surgery.

Intrasphincteric injection of botulinum toxin type A has shown to effectively reduce LES pressure by inhibiting cholinergic receptors. Pasricha et al. reported a 70% symptomatic relief in patients treated with botulinum toxin with 40% requiring more than one injection [94]. Despite impressive early results, the long-term efficacy of this treatment has been questioned based on high 1-year relapse rates and less successful repeat injection. Older patients and patients with vigorous achalasia have a better response to botulinum therapy [95]. Elderly patients (>60 years) with significant medical problems tolerate this treatment modality well [96, 97]. Advantages of this procedure are: it is well tolerated with minimal complications and is a good option in elderly patients that cannot tolerate dilatation and surgery. On the other hand, relapse rates are high and frequent injections may be necessary which could lead to patient discomfort and increased costs.

Pneumatic balloon dilatation has wide acceptance and is a mainstay of treatment for achalasia. This technique employs a rapidly inflated balloon in the distal esophagus to dilate and disrupt the circular smooth muscle fibers of the LES.

The procedure is well tolerated with a short-hospital stay. The first dilatation results in symptom relief in 50–65% of patients [71]; however, 15–48% of patients require repeat procedures [98–100]. Patients older than 40 years had better 2-year results than patients younger than 40 (67 vs. 29%) [101]. The principal risk of pneumatic dilation is esophageal perforation, which in skilled hands is less than 2%. The risk of perforation is highest with the first dilatation.

Surgical Treatment

Surgical treatment of achalasia consists of longitudinal division of the LES muscle fibers also referred to as *myotomy* or *esophagomyotomy*. This procedure lowers LES pressure and esophageal intraluminal pressure, but most importantly eradicates the effects of incomplete LES relaxation. Good-to-excellent results have been reported in as high as 90% of patients with 1–36 years' follow-up of. Follow-up studies have demonstrated an improvement in esophageal emptying, increased LES diameter, and decreased esophageal diameter [102–105]. Although the point in a patient's care at which surgery should be offered is undefined, superior results with laparoscopic myotomy as initial therapy, as compared to pneumatic dilatation and botulinum toxin, have been suggested [106]. Furthermore, Smith et al. reported that complication rates after laparoscopic Heller myotomy were higher among patients who underwent previous endoscopic treatment with GI perforation being the most common complication (9.7 vs. 3.6%) [107].

Laparoscopic esophagomyotomy is currently the most frequently used surgical approach for achalasia, with decreased postoperative pain, length of hospitalization, and technical ease, compared to open and thoracoscopic methods. Current data indicate that laparoscopic myotomy is a safe and effective option in elderly patients. Kilic et al. reported that in 57 patients >70 years of age who underwent laparoscopic Heller myotomy, there were no perioperative deaths and that there was a 19.3% complication rate and median hospital stay of 3 days. At a mean follow-up of 23.5 months 96.5% reported improvement in symptoms [108]. Severe preoperative dysphagia, dilated esophagus, and absence of all motility are predictors of poor outcome, and LES pressure >35 mmHg is a predictor of good outcome after Laparoscopic Heller myotomy [109, 110]. The overall complication rate for esophagomyotomy is 10%, with GERD being the most common postoperative problem followed by dysphagia from insufficient myotomy [102]. Although partial fundoplication (Dor vs. Toupet) may substantially reduce postoperative reflux with esophagomyotomy, the potential for residual dysphagia has tempered its use.

Diffuse Esophageal Spasm

Diffuse esophageal spasm (DES) is a primary esophageal hypermotility disorder characterized by dysphagia and episodic substernal chest pain. It is a rare condition, the etiology of which is unknown. Although the mean age of occurrence is in the 5th decade, it can in the elderly patients up to the 8th decade of life. Because the symptom that most often brings DES patients to medical attention is angina-like chest pain, formal workup for a cardiac etiology is almost always undertaken. The principal manometric findings in DES are frequent simultaneous and repetitive contractions of abnormally high amplitude or long duration. The finding of 20% or more simultaneous contractions per 10 wet swallows is considered diagnostic of the disorder [111]. LES resting pressures and relaxation with swallows are usually normal. DES activity is intermittent and ambulatory 24-h manometry allows patients to go about their daily activities and receive whatever typical stimuli are necessary to precipitate an episode [112]. Many patients with DES have an underlying psychiatric history with diagnoses that include depression, psychosomatic complaints, and anxiety. These diagnoses have been reported in 80% of patients with manometric contraction abnormalities [113].

A barium esophagram can help in the characterization of DES. Occasionally, a "corkscrew" esophagus caused by segmental contractions of circular muscle is identified. The finding of an esophageal pulsion diverticulum in a patient with characteristic chest pain is virtually diagnostic of DES. Esophagoscopy should be performed in all patients to exclude the possibility of a tumor, fibrosis, or esophagitis, which might cause esophageal narrowing that may be associated with proximal tertiary esophageal contractions.

Treatment of this condition may be difficult. As with achalasia, some patients respond to sublingual nitrates or calcium channel blockers before meals [114, 115]. Esophageal dilation may alleviate symptoms of dysphagia for days to months and can be repeated for continued relief [116]. However, there is an increased risk of perforation with multiple dilations of a hypertrophic, spastic esophagus.

Surgical treatment is generally reserved for medical and endoscopic treatment failures. This consists of a long myotomy aimed at reducing simultaneous contractions and improving compliance, at the cost of peristaltic loss and reduced residual muscular contraction amplitude [117]. It can be accomplished thoracoscopically [118], with an 80% rate of diminished symptoms during the early postoperative period. Fundoplication may be performed to avoid reflux, but with the same concerns expressed for achalasia. With long durations of follow-up (5.0–10.7 years), surgically treated patients can remain free of chest pain and dysphagia [119].

Other Esophageal Disorders

Nutcracker esophagus is another primary esophageal hypermotility disorder that like DES presents as episodic dysphagia and chest pain. It tends to occur later than DES (5th and 6th decades of life) and can occur in elderly patients as well. It is diagnosed by manometry when average peristaltic pressures are above 180 mmHg and have a prolonged duration. Treatment is similar to DES.

Secondary esophageal dysmotility disorders occur in conjunction with systemic diseases such as diabetes, hypo- and hyperthyroidism, systemic sclerosis, polymyositis, and amyloidosis. These diseases are prevalent in the elderly and should be kept in mind while working up a patient for a suspected esophageal motility disorder [120].

Benign Tumors of the Esophagus

Benign tumors of the esophagus often go unreported and undiagnosed, their exact incidence is not known. In two large autopsy series, the reported incidences of these tumors were 0.45 and 0.59% [121, 122]. They can be intraluminal, intramural, or extramural. The most common benign tumors of the esophagus are leiomyomas, followed by fibrovascular polyps.

Leiomyomas

Leiomyomas are mesenchymal in origin and account for two-thirds of all benign esophageal tumors. The peak incidence for leiomyomas is between the ages of 30 and 59, but can occur in much older patients [123]. In a review of 838 cases, 56% were found in the lower third of the esophagus, 33% in the middle third, and 11% in the upper third [124]. Majority of leiomyomas are intramural and arise from the muscularis propria, but they can also rise from the muscularis mucosa. Esophageal leiomyomas grow slowly and 50% of cases are less than 5 cm in size [124] and in some instances maybe as large as 15 cm. They can be single or multiple, spherical well-circumscribed intramural, pedunculated intraluminal, or annular masses.

The most common symptoms are dysphagia (46.9%) and retrosternal or epigastric pain (46.7%). Other symptoms associated with leiomyomas are weight loss, nausea, vomiting, reflux, ulceration, and bleeding [123]. Symptoms do not necessarily correlate with size [123, 125].

Large leiomyomas may present as rounded or lobulated lateral mediastinal growths on chest radiography, this is usually an incidental finding in asymptomatic patients. Barium swallow is the first diagnostic test performed in patients with

symptoms suspicious for benign esophageal tumors. Leiomyomas present as a well-circumscribed smooth filling defects with normal overlying mucosa on swallows. Endoscopy confirms the tumor location and further evaluates the mucosa overlying the mass. Mucosa is usually normal and moves freely over the mass in leiomyomas, one may observe luminal narrowing. However, mucosal irregularity, ulceration, and luminal stenosis with obstruction are suspicious for a malignant lesion. Endoscopic ultrasonography is useful in differentiating extrinsic vs. esophageal wall tumors and in delineating their layer of origin. Leiomyomas are well-demarcated, uniform, hypoechoic masses, which may arise from the muscularis mucosa or muscularis propria [126, 127]. Identification of leiomyomas that originate in the muscularis mucosa permits consideration of endoscopic removal, while those that originate from the muscularis propria require more invasive surgical enucleation [128]. Computed tomography provides information regarding size, location, and anatomic relationships that may aid in operative planning. Endoscopic biopsy or endoscopic ultrasound guided fine needle aspiration may provide a definitive tissue diagnosis. This should be reserved for lesions suspicious for malignancy as preoperative endoscopic biopsy is associated with an increased incidence of intraoperative mucosal tears [129].

Indications for surgical treatment are unremitting symptoms, increasing tumor size, mucosal ulceration to obtain histological diagnosis and facilitation of other procedures. Although controversial, asymptomatic patients should be managed nonoperatively with periodic radiological follow-up [130]. Symptomatic leiomyomas should be enucleated after performing a longitudinal esophageal myotomy, care should be taken to avoid mucosal injury. Myotomy should be reapproximated to avoid mucosal bulging and postoperative dysphagia. Tumors in the upper and middle third of the esophagus are approached from the right side of the chest, tumors in the lower third are approached from the left, and tumors at the GEJ can be resected through an upper midline abdominal incision. Tumors larger than 8 cm and those that are firmly adherent to the mucosa may necessitate esophageal resection [124, 131]. Resection can be achieved via open and minimally invasive techniques. Thoracoscopic approach has been gaining popularity because of its association with decreased hospital length of stay and postoperative pain in comparison to open procedures [129]. Overall patients tolerate resection well with minimal complications, good symptom relief, and no recurrences [130].

Fibrovascular Polyps

Fibrovascular esophageal polyps are intraluminal polyploid lesions that appear most commonly in the upper esophagus

near the cricopharyngeus muscle. These lesions occur predominantly in men during the sixth and seventh decades, but are also encountered in much older patients. As a group they include fibromas, fibrolipomas, myomas, myxofibromas, pedunculated lipomas, and fibroepithelial polyps [132, 133]. Early lesions consist of nodular submucosal tissue that may over time elongate into a pedunculated polyp. The geometric forces of peristalsis eventually cause the tip of the polyp to reach the distal esophagus.

Fibrovascular polyps come to medical attention when large enough to cause intermittent dysphagia, substernal fullness, or regurgitation of recently ingested material. The presentation may be more acute if a pedunculated polyp obstructs the esophagogastric junction or becomes ulcerated and bleeds. Although rare, regurgitation of the tumor and asphyxiation secondary to acute glottic obstruction are an additional concern [134]. A barium esophogram demonstrates the smooth polypoid intraluminal filling defect. Upper endoscopy can also be used to visualize the polyp and permits the stalk to be traced to its level of attachment [135].

Fibrovascular polyps are resected to relieve symptoms and prevent aspiration and asphyxiation. The greatest polyp size that might be amenable to endoscopic excision is dictated by the polyp's architecture and location and by the endoscopist's skill. Surgical treatment is undertaken when endoscopic removal is unfeasible. The standard approach is through a cervical incision on the side of the neck opposite the stalk attachment. An esophagomyotomy is performed below the cricopharyngeal muscle, and the polyp is delivered into the wound and amputated at the stalk base. If the base is a significant distance below the cricopharyngeus, a right transthoracic approach can be used.

Chapter 60

Esophageal Cancer in the Elderly

Philip A. Rascoe, John C. Kucharczuk, and Larry R. Kaiser

Neoplasms of the esophagus and gastroesophageal junction are aggressive tumors that often present at an advanced stage and that historically have been associated with poor survival despite therapy. Surveillance, Epidemiology and End Results (SEER) data from the National Cancer Institute estimate that 16,470 Americans are diagnosed with and 14,280 die of esophageal cancer annually. Moreover, the incidence of esophageal cancer is increasing, with an annual percentage change of +0.5% between 1975 and 2005. SEER data also demonstrate that esophageal cancer is primarily a disease of the elderly. From 2001 to 2005, the median age at diagnosis for cancer of the esophagus was 69 years, with 61.5% of those diagnosed being age 65 or older (Fig. 60.1) [1]. According to US Census Bureau projections, we can expect our population to be older by midcentury. In 2000, 12% of

the population was 65 or older. In 2030, when all of the baby boomers will be 65 or older, this age group will represent 20% of the US population. This age group is projected to increase to 88.5 million in 2050, more than doubling the number in 2008 (38.7 million) [2]. It is apparent that surgeons should expect to see an ever-increasing number of patients with esophageal cancer. With earlier identification due to surveillance of premalignant disease and improved treatment strategies, some improvement in survival has been made over the past two decades (Fig. 60.2). However, most patients still present at an advanced stage. Surgeons will continue to play a significant role in the management of these patients, performing potentially curative extirpation in those with early stage disease, and palliative procedures in those with advanced malignancy.

CASE STUDY

A 79-year-old Caucasian gentleman was referred by his gastroenterologist for a surgical opinion. He had suffered with severe gastroesophageal reflux for many years, despite therapy with antacids, H2-blockers, and proton-pump inhibitors. One year ago, while taking 20 mg of omeprazole daily, he underwent upper endoscopy which revealed Barrett's esophagus and low-grade dysplasia. His daily dose of omeprazole was escalated to 40 mg. Upper endoscopy was recently repeated revealing progression of disease, with biopsy-proven multifocal high-grade dysplasia. Examination in the office revealed a slightly obese, but otherwise healthy-appearing individual. His past medical history was significant only for hypertension and hypercholesterolemia, both of which were well-controlled with medication. Detailed discus-

sion focused on the premalignant nature of his disease, and his significant risk (40–50%) of harboring esophageal adenocarcinoma. He was loath to undergo less-proven options such as endoscopic PDT or mucosal resection. He accepted advisement that he have an esophagectomy after careful discussion of the risks, including morbidity as high as 40% and mortality of at least 5%. Preoperative serology, hemogram, CXR, and CT of the chest, abdomen, and pelvis were unremarkable. He was referred to a cardiologist for preoperative clearance and a noninvasive stress test revealed no evidence of reversible cardiac ischemia. He underwent transhiatal esophagectomy (THE), esophagogastric anastomosis, and feeding jejunostomy. His postoperative course was complicated by atrial fibrillation requiring management with amiodarone but was otherwise uneventful. Barium esophagram on postoperative day 7 revealed no evidence

CASE STUDY (continued)

of anastomotic leak, and he was discharged on postoperative day 9 tolerating a postesophagectomy diet and jejunostomy feeding. At the time of his 3-week postoperative visit, he had discontinued his tube feeds and was

maintaining his weight with five small daily meals. His jejunostomy tube was removed at this visit. Final pathology revealed T1N0 adenocarcinoma of the distal esophagus with negative resection margins, and he was advised that he needed no adjuvant therapy. He is scheduled for return office visit in 3 months with a CXR.

Histologic Classification, Location, and Incidence

Malignant neoplasms of the esophagus include epithelial tumors (such as adenocarcinoma, squamous cell carcinoma, and small-cell carcinoma), sarcomas, lymphomas, and metastatic lesions from distant primary sites (Table 60.1). Adenocarcinoma and squamous cell carcinoma are the most frequent malignant lesions, and adenocarcinoma has emerged in recent years as the more common lesion (Fig. 60.3). In fact, the incidence of esophageal adenocarcinoma has increased in the last 25 years greater than the incidence of any other major malignancy in the USA (Fig. 60.4) [3]. Most thoracic surgeons will complete an entire career without seeing the less common types of esophageal malignancies. In this chapter, the focus is diagnosis and management of esophageal squamous cell carcinoma and adenocarcinoma.

The distribution of esophageal cancers along the esophagus is different and somewhat characteristic. Squamous cell cancer occurs most commonly in the middle third of the

esophagus. Postlethwaite [4], in a collective review of more than 28,000 patients with squamous tumors, reported these tumors to be in the upper, middle, and lower esophagus in 15, 50, and 35% of patients, respectively. Adenocarcinoma, on the other hand, tends to involve the lower esophagus. Ming [5], reviewing a series of 4,783 patients with adenocarcinoma, showed the tumor to be in the lower third in 67%. Small-cell cancers occur with equal frequency in the middle and lower thirds, with the upper third involved in fewer than 5% of cases [6]. Esophageal melanoma and choriocarcinoma, though rare, seem to be most prevalent in the lower third. No specific pattern of distribution has been noted for esophageal sarcomas, lymphomas, or metastases.

There have been several consequences of the increasing prevalence of adenocarcinoma. Patients with adenocarcinoma are more likely to be treated surgically than patients with squamous cell carcinoma. Therefore the predominance of adenocarcinoma in many US surgical series results from two factors: an overall increase in the prevalence of adenocarcinoma since 1978 and an increase in the likelihood of resection

FIGURE 60.1 Age-specific incidence of esophageal cancer (2000–2005) [1].

FIGURE 60.4 Relative change in incidence of esophageal adenocarcinoma and other malignancies (1975–2001). Data from the National Cancer Institute’s Surveillance, Epidemiology, and End Results program with age-adjustment using the 2000 US standard population. Baseline was the average incidence between 1973 and 1975. *Solid black line*=esophageal adenocarcinoma; *short dashed line*=melanoma; *line*=prostate cancer; *dashed line*=breast cancer; *dotted line*=lung cancer; *dashes and dotted line*=colorectal cancer (from [3], reprinted with permission of Oxford University Press).

for patients with these tumors. As adenocarcinoma invariably involves the lower third of the esophagus and esophagogastric junction, both the tumor and the regional lymph nodes are accessible through an abdominal approach and are suitable for resection using the THE technique. With the option of avoiding thoracotomy (using the THE approach), many elderly patients who otherwise may not have been a candidate for surgical therapy may now be offered esophagectomy.

Pathogenesis

The exact etiology of esophageal cancer is unknown. The data support the hypothesis that the more common epithelial tumors arise as a result of chronic irritation of the esophagus from a wide range of behavioral, nutritional, and environmental sources, and that the likelihood of developing cancer may be increased in immunocompromised patients. Tobacco, alcohol, and obesity are all risk factors associated with the development of esophageal cancer [7]. Table 60.2 shows the additional risk factors associated with esophageal cancer and their contributions to the development of either squamous cell carcinoma or adenocarcinoma.

The relationship between smoking and the development of squamous cell cancers is well documented for both men and women [8–12]. Choi and Kahyo [9] have shown a

TABLE 60.2 Risk factors for the development of esophageal cancer with their relevant contribution to both squamous cell and adenocarcinoma of the esophagus

Risk factor	Squamous cell carcinoma	Adenocarcinoma

dose-dependent relation between the amount of smoking and the risk of developing cancer, and they have shown that this risk decreases with smoking cessation. Smokeless tobacco products have also been shown to increase the risk of cancer of the oropharynx, larynx, and esophagus [13]. Numerous studies have documented the relationship between alcohol consumption and squamous cell cancer [9–12, 14, 15]. As with smoking, the risk appears to be dose dependent. These risk factors, alcohol consumption and smoking, are additive. Other factors implicated in the development of squamous cell cancer are diet, including meal composition, consistency, temperature, and rate of consumption, achalasia, lye ingestion, radiation therapy, Plummer–Vinson syndrome, and prior head and neck squamous cell cancer. Although many have postulated a genetic predisposition to esophageal cancer, tylosis is the only recognized familial syndrome that predisposes to the development of esophageal cancer. This is an autosomal dominant disorder, which has been mapped to chromosome 17q25 [16]. Patients have hyperkeratosis of the palms of their hands and the soles of their feet. The risk of developing squamous cell carcinoma of the esophagus by age 70 is 95% in this cohort of patients [17].

Obesity and Barrett's or columnar-lined esophagus are associated with an increased risk of developing adenocarcinoma of the esophagus. Chronic gastroesophageal reflux disease (GERD) is considered the predominant contributor to the development of Barrett's metaplasia. The frequency, severity, and duration of reflux symptoms are correlated with an increased risk of developing esophageal adenocarcinoma [18]. Patients with recurring symptoms of reflux have an eightfold increase in the risk of esophageal adenocarcinoma. Barrett's esophagus develops in about 5% of patients

with GERD. Endoscopically, it is recognized by inflamed salmon-colored mucosa extending proximally from the GE junction. Often there are intervening areas of normal-appearing mucosa, or so-called skip areas. Figure 60.5a shows the typical endoscopic appearance; Fig. 60.5b shows the same patient with methylene blue vital stain, which can be used to highlight the mucosal changes. Microscopic evaluation reveals replacement of the normal stratified squamous epithelium of the esophagus with columnar epithelium more typical of other parts of the gastrointestinal tract. Thus, these changes are often referred to as "intestinalization" of the mucosa. With progression to dysplasia, the nuclei become "crowded" and the normal glandular architecture is lost. Histologically, patients with high-grade dysplasia carry a significant risk for esophageal carcinoma and should be considered candidates for resection. Approximately 10–30% of patients with high-grade dysplasia will develop invasive adenocarcinoma within 5 years of the initial diagnosis; moreover, in patients undergoing esophagectomy for presumed high-grade dysplasia, invasive carcinoma is identified in 30–40% of the pathologic specimens [19]. Barrett's esophagus increases the risk of esophageal adenocarcinoma 30- to 40-fold when compared with the general population [20]. The annual rate of neoplastic transformation to adenocarcinoma in patients with Barrett's is 0.5% [21]. A great deal of progress has been made in understanding columnar-lined esophagus since the entity was first described by Barrett in 1950 [22]. However, many questions remain including why Barrett's esophagus and adenocarcinoma affect primarily Caucasian men, why only some patients progress to dysplasia and adenocarcinoma, and how long this process takes.

Diagnosis

Unfortunately, early esophageal carcinoma is largely asymptomatic. As a distensible muscular tube, a significant portion of the esophageal lumen must be obstructed to impede passage of a food bolus and produce symptoms. Dysphagia is the primary manifestation of esophageal cancer in 80% of patients and up to 20% have odynophagia. Vague symptoms of retrosternal discomfort and transient dysphagia are often overlooked by the patient and the physician. On retrospective evaluation, many patients have significantly altered their eating habits by avoiding foods such as meats and breads while increasing their intake of semisolid foods and liquids. About one-half of patients have significant weight loss. Weight loss of more than 10% of body mass is an independent predictor of poor prognosis [23].

Pulmonary symptoms may be caused by aspiration of regurgitated food or by direct invasion of the airway by esophageal tumor, resulting in an esophagorespiratory fistula. Direct invasion through the membranous airway can occur with locally advanced lesions, usually involving the trachea or left mainstem bronchus as it passes anterior to the esophagus. Patients with cancers involving the upper thoracic esophagus must undergo preoperative bronchoscopy to rule out airway involvement as this precludes resection. Although flexible bronchoscopy may demonstrate gross airway invasion, rigid bronchoscopy is much more sensitive in determining adherence to the membranous trachea. Loss of the normal “ripple” effect as the rigid scope slides over the membranous trachea and left main bronchus suggests the tumor is fixed to the airway and is not resectable.

New hoarseness due to vocal cord paralysis is indicative of left recurrent nerve involvement and suggests unresectability. Virchow’s node, a palpable left supraclavicular lymph node, may be apparent in some patients. Fine-needle aspiration with positive cytology confirms the pathologic involvement of Virchow’s node, which is considered distant metastatic

disease and precludes resection. Symptoms of metastatic disease vary depending on the site. The most common sites and associated symptoms include celiac lymph nodes or liver with epigastric or right upper quadrant pain, pulmonary or pleural space metastases with shortness of breath and chest pain, and bone metastases with localized, severe pain.

The evaluation of a patient with suspected esophageal cancer involves securing the diagnosis, clinically staging the patient, and determining the medical operability of patients with stage-appropriate lesions for resection. Barium swallow and esophagoscopy remain the most important diagnostic tools for assessing the patient with esophageal symptoms. Barium swallow is usually the first study obtained. It provides both anatomic and functional information. A localized, concentric, “apple-core” narrowing of the esophagus is highly suggestive of carcinoma. Some benign diseases, such as a peptic stricture and achalasia, may mimic cancer. Therefore, flexible esophagogastroduodenoscopy (EGD) and biopsy are required to confirm the diagnosis, precisely locate the lesion, and rule out concurrent gastric disease that would preclude using the stomach as a conduit. Endoscopic information that should be noted and recorded includes the proximal and distal extent of the tumor and the presence and location of concurrent esophageal or gastric pathology (e.g., Barrett’s mucosa). In patients considered for surgical resection, endoscopic ultrasonography (EUS) is the single most valuable test in determining tumor size and depth of penetration (T stage). EUS successfully predicts the T stage in greater than 80% of cases confirmed at surgery, and generally performs better for advanced (T4) than local (T1) disease. Regional lymph nodes are also visualized during EUS and can be sampled by FNA to determine the cytologic presence or absence of metastatic nodal disease (N stage). The sensitivity of EUS alone to predict N stage is 85% and improves to greater than 95% with FNA [24]. Figure 60.6 is an example of EUS for esophageal cancer.

FIGURE 60.6 Endoscopic image (a) and endoscopic ultrasound (b) showing a transmurular adenocarcinoma of the esophagus associated with Barrett’s esophagus (*short arrows*), with lymph-node metastasis

(*long arrow*) (image courtesy of John R. Saltzman, M.D., Assistant Professor of Medicine, Harvard Medical School; from [7]).

A computed tomographic (CT) scan of the chest, abdomen, and pelvis with intravenous contrast is valuable for assessing lung and liver metastasis. However, it is not accurate for determining T stage or assessing regional lymph node involvement.

Positron emission tomography (PET) with 18F-fluorodeoxyglucose (FDG) is a physiologic test unique in its ability to detect increased metabolic activity within tissues. It is increasingly used to detect distant metastasis (M stage) in patients with esophageal cancer. It has been reported that PET will detect otherwise radiographically occult metastatic disease in up to 15% of patients who were thought to have only localized disease by conventional studies, thus making them more appropriately managed by nonsurgical interventions [25]. We now routinely obtain a PET scan as part of the preoperative staging evaluation in patients under consideration for esophagectomy. Increasingly, PET is being used to restage patients and evaluate response after neoadjuvant chemoradiation. Several studies have shown promising results in demonstrating that decreased FDG avidity after neoadjuvant therapy predicts pathologic response and increased survival [26, 27].

The use of combined thoracoscopy and laparoscopy for preoperative staging has been advocated by some centers. Periesophageal mediastinal lymph nodes and celiac lymph nodes can be sampled with a high degree of accuracy using these techniques [28]. This practice has largely been replaced by the combination of EUS–FNA and PET. We currently do not use these techniques as part of our standard evaluation.

Unfortunately, no serum tumor markers have been consistently found in patients with esophageal cancers. Standard serum cancer markers including CEA, CA 19-9, and CA 125 have no value in the preoperative evaluation of patients with esophageal cancer.

Staging

Esophageal cancers are staged according to the American Joint Committee on Cancer (AJCC) TNM staging system [29]. The staging system for esophageal cancer has recently undergone revision. Pathologic stage according to the updated system is dependent upon the number of nodes containing metastasis, tumor grade, tumor location, and histologic cell type. The current (seventh edition) AJCC TNM definitions are shown in Table 60.3. The stage groupings according to histology are displayed in Table 60.4. It is clear that the outcome in esophageal cancer is strongly associated with the stage of disease. Thus, accurate clinical staging is of paramount importance in formulating an appropriate

TABLE 60.3 American Joint Committee on Cancer (AJCC) staging of esophageal cancer: TNM definitions

Stage	Description
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia ^a
T1	Tumor invades lamina propria, muscularis mucosa, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosa
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Resectable tumor invading pleura, pericardium, or diaphragm
T4b	Unresectable tumor invading other adjacent structures, such as aorta, vertebral body, trachea, etc.
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in 1–2 regional lymph nodes
N2	Metastasis in 3–6 regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

treatment plan and providing the patient with information regarding prognosis. In stage-appropriate candidates, plans are made to optimize the patient from a medical standpoint and proceed to resection. The role of preoperative therapy followed by operation remains ill defined and hotly debated.

Analysis of Comorbidities and Medical Clearance

Esophagectomy for carcinoma is a major surgical endeavor and causes significant physiologic stress to the patient. As such, it is associated with considerable morbidity and mortality. As the majority of patients presenting for resection are

^aOr mixed histology including a squamous component or NOs

^bLocation of the primary cancer site is defined by the position of the upper (proximal) edge of the tumor in the esophagus

over the age of 65, they commonly have comorbidities such as hypertension, diabetes mellitus, cardiac disease, and pulmonary dysfunction. Moreover, all elderly patients have measurable diminution in cardiovascular, pulmonary, and renal physiology [30]. Careful patient selection and medical optimization of existing comorbidities is of paramount importance in maintaining acceptable surgical outcomes, especially in the elderly. All patients have basic laboratory tests (serum chemistries, CBC, and PT/PTT), EKG, CXR, and pulmonary function studies preoperatively. Younger patients with cardiac risk factors and all elderly patients are referred to a cardiologist for operative clearance. Most

undergo provocative screening to identify reversible ischemic heart disease. Unless contraindicated, perioperative beta-blockade is implemented.

Therapy

The goal of any therapy designed to manage patients with esophageal cancer is to relieve symptoms and treat the underlying cancer. The purpose of this chapter is not to present an exhaustive review of all treatment modalities but to cover those which are applicable in the elderly patient. It is

important for elderly patients and their families to be aware of their treatment options so the choice of therapy fits the patient's desires, lifestyle, and personal and family support systems.

Surgery

Surgery has emerged as the best single-modality therapy for patients with esophageal cancer in terms of durable control of dysphagia and survival. Multiple factors influence the surgical approach to an esophageal malignancy. These include the nature and location of the neoplasm, the overall health of the patient, and the expertise of the surgeon. Several surgical approaches have been described. These include the transhiatal approach [31], the transabdominal transthoracic approach (Ivor Lewis) [32], the three-stage or "three-hole" approach (McKeown) [33], the thoracoabdominal approach, and the minimally invasive approach. These operations all include subtotal esophageal resection and resection of the esophagogastric junction, gastric cardia, and regional lymph nodes (Fig. 60.7). The incisions used for these techniques are demonstrated in Fig. 60.8. Each approach has its own set of risks and benefits as well as outspoken opponents and proponents. Selection of the appropriate approach requires experienced surgical judgment. Despite the rhetoric, several studies have shown equivalent outcome among the multiple approaches. It appears that the experience of the surgeon [34] and the number of cases performed at a particular institution are the leading factors determining outcome [35]. Clearly, failures in technique that occur during the performance of an esophagectomy are associated with increased length of hospital stay and increased in-hospital mortality and are predictive of a poorer overall long-term survival [36].

Options for reconstruction include gastric tube, colonic interposition, and small intestinal free graft. Because of its ample blood supply, ease of mobilization, and sufficient length to reach the neck, the gastric tube is the usual conduit of choice for reconstruction. The use of colon is more complex and has increased morbidity when compared to gastric pull-up [37]. We reserve the use of colon or jejunum for patients with an unusable stomach due to previous surgery, tumor extension, or other technical considerations.

The esophageal anastomosis requires meticulous attention. Many esophageal operations are plagued by high anastomotic leak rates and a significant number of postoperative strictures. At present, the modified stapled anastomosis [38] as described by Orringer appears to have the lowest leak rate, about 3% as compared with sutured techniques, which are as high as 15%. Many thoracic surgeons have adopted this anastomotic technique.

FIGURE 60.7 Standard esophagectomy for cancer involves subtotal esophagogastric resection along with removal of the regional lymph nodes. Different incisional approaches result in variations in the amount of resected esophagus and the level of the esophageal anastomosis (reprinted from [67], with permission from Elsevier).

FIGURE 60.8 Incisions used for the more common esophagectomy techniques (from [68], with permission).

The transhiatal approach. The THE was reintroduced by Orringer and Sloan [31] in 1978 and continues to be refined [38–40]. THE does not require a thoracotomy. As such, THE may be cautiously offered to some elderly and high-risk

patients who otherwise would not be candidates for surgery. Indications for THE include benign or malignant esophageal pathology usually involving the distal half of the intrathoracic esophagus in which there are options for long-segment esophageal replacement. The procedure is performed through an upper midline laparotomy and left cervical incision. A gastric conduit based on the right gastroepiploic artery is used to establish gastrointestinal continuity. If the stomach is unusable, a colonic interposition can be performed. Advantages of the THE approach are that (1) it avoids thoracotomy, which results in less short-term incisional pain, reduced narcotic requirement, and greater mobility and independence; (2) it uses a cervical esophageal anastomosis, which minimizes the adverse consequences of anastomotic leakage; and (3) gastric pull-up with cervical esophagogastric anastomosis results in reliable and durable quality of swallowing. Disadvantages are that (1) it requires long-segment esophageal replacement; (2) it is associated with a risk of ipsilateral recurrent laryngeal nerve injury; (3) there is a chance of intrathoracic injury from the “blunt” transhiatal dissection; and (4) complete intrathoracic lymphadenectomy is difficult to achieve.

The Ivor Lewis approach. Partial esophagogastric resection using midline abdominal and right thoracotomy incisions, also known as the Ivor Lewis [32] technique, is designed to optimize exposure of the intrathoracic esophagus, which passes through the upper two-thirds of the chest along the right posterior mediastinum. The involved portion of esophagus is freed from the mediastinum and resected along with the esophagogastric junction, proximal cardia, and regional lymph nodes. The resected esophageal segment is replaced most commonly by stomach, which is mobilized and passed into the chest along the esophageal bed and anastomosed to the proximal esophagus near the level of the azygous vein. The advantage of Ivor Lewis esophagectomy (ILE) is the excellent exposure of the mid- to upper intrathoracic esophagus and lymph nodes. The disadvantages are (1) postthoracotomy pain; (2) the potential for intrathoracic esophageal anastomotic leak; and (3) a moderate amount of thoracic esophagus is retained with this approach and may be at risk of recurrent disease, specifically in the setting of severe Barrett’s esophagus.

Three-field esophagectomy. This approach is carried out through separate laparotomy, right thoracotomy, and cervical incisions [33]. Proponents of this approach fall into two categories. The first group utilizes this approach to resect large intrathoracic lesions of the mid-esophagus. Exposure, especially at the level of the carina and left mainstem bronchus, is superior as compared with the transhiatal approach. Because visualization is improved, the injury rate to nearby structures, especially the airway and azygous vein, is lower. This approach has the benefits of both ILE and THE, as direct visualization of the mid-esophagus is obtained

while allowing for cervical esophagogastric anastomosis. The second group utilizes this approach to perform a complete two- or three-field lymph node dissection, suggesting that this approach provides a more complete resection and thus improves long-term survival. This approach has been shown to have acceptable morbidity and mortality as compared with other approaches; however, the often-cited report was from a single US center [41]. On the other hand, a large randomized Dutch trial comparing transhiatal resection with extended transthoracic resection showed that the transhiatal approach was associated with a lower morbidity and no statistically different overall, disease-free, and quality-adjusted survival [42]. Patients who underwent thoracotomy had an increased incidence of chyle leak and pulmonary complications, as well as longer ventilator-dependence, ICU stay, and hospital stay. A meta-analysis by the same group demonstrated no difference in survival at 3 and 5 years [43]. The statistically significant differences in morbidity and mortality from the meta-analysis are demonstrated in Table 60.5. In a recent retrospective review of 2,303 esophageal cancer patients treated with R0 resection without adjuvant or neoadjuvant therapy, the number of nodes removed was an independent predictor of survival. The authors concluded that to maximize this survival benefit, a minimum of 23 nodes should be removed at esophagectomy [44]. The true value of extensive lymphadenectomy in esophageal cancer remains undefined.

The thoracoabdominal approach. The left thoracoabdominal approach is probably the least utilized of all approaches to the esophagus. It is performed by making an oblique incision from the midpoint between the xiphoid and umbilicus across the costal arch to the tip of the scapula. The abdomen is opened, the costal arch is divided, and the chest is entered through the seventh intercostal space. The diaphragm is opened in a circumferential manner along the chest wall to avoid any damage to the phrenic nerve branches. At least a 2-cm rim of diaphragm is preserved on the chest wall to aid in reconstruction of the diaphragm at the completion of the

TABLE 60.5 Transthoracic esophagectomy vs. transhiatal esophagectomy for carcinoma – a meta-analysis (7,527 patients)

	Transthoracic	Transhiatal
In-hospital mortality	9.2%	5.7%
Blood loss (mL)	1,001	728
Pulmonary complications	18.7%	12.7%
Chylothorax	2.4%	1.4%
Intensive care unit stay (days)	11.2	9.1
Hospital stay (days)	21.0	17.8
Anastomotic leak	7.2%	13.6%
Vocal cord paralysis	3.5%	9.5%
3-year survival	26.7%	25.0% (ns)
5-year survival	23.0%	21.7% (ns)

Source: From [43], reprinted with permission from Elsevier

procedure. This approach offers superior exposure to the left upper quadrant, including the hiatus, and is our approach of choice in patients with previous extensive hiatal or proximal gastric surgery. For patients with distal tumors and inadequate conduit for total esophageal replacement, the anastomosis can be placed in the left chest below the inferior pulmonary vein or up to the level of the aortic arch. For those with adequate conduit, a separate left cervical incision can be made and the cervical esophago-gastric anastomosis can be placed in the neck. A consecutive case series of 64 thoracoabdominal esophagectomies reported no anastomotic leaks and a 2% mortality rate [45].

Minimally invasive esophagectomy. A number of minimally invasive techniques to esophagectomy have been described. These include laparoscopic, hand-assisted, thoracoscopic, and robotic-assisted esophagectomy. The hope of these procedures is that minimizing the incision size will decrease the morbidity of the operation while at the same time providing adequate resection. The largest study included 217 patients from the University of Pittsburgh who underwent esophagectomy via thoracoscopy, laparoscopy, and a left neck incision [46]. The investigators observed equivalent results as compared to open techniques and suggest development of a multicenter trial to define the role of minimally invasive esophagectomy. At present, the advantage of this approach remains to be determined.

Esophagectomy in the Elderly

As previously stated, elderly patients presenting for esophagectomy often have pre-existing cardiopulmonary comorbidities. However, whether postsurgical outcome in the elderly is worse than for younger patients remains controversial.

In a retrospective review by Ruol et al., of 1,400 patients presenting with esophageal cancer over the course of 13 years, there was no difference in morbidity (~49%), 30-day mortality (1.9%), or 5-year survival (~34%) in postesophagectomy patients 70 or older when compared to the group younger than 70 [47]. As discussed in this paper, a significantly higher percentage of patients in the younger age group underwent esophagectomy, indicating that these results were obtained in a highly selected group of elderly patients. This underscores the importance of preoperative risk assessment, but also demonstrates that long-term survival of elderly esophageal cancer patients who tolerate esophagectomy is independent of age alone.

A retrospective review of the experience at Roswell Park Cancer Institute revealed similar results. The percentage of patients older than 70 who were deemed surgical candidates was statistically lower than younger patients. Overall morbidity, mortality, and survival were equivalent in the two surgical groups, with only atrial fibrillation and myocardial infarction being increased in the elderly [48].

In contrast to the previous two studies, experience at Memorial Sloan-Kettering Cancer Center revealed that older patients had longer length of hospital stay and worse postoperative mortality. In particular, their octogenarian cohort had a perioperative mortality of almost 20%, as well as an overall shorter disease-free survival [49].

In analyzing surgical outcome in 1,777 esophagectomy patients from the Veterans Affairs (VA) Medical Centers, the largest cohort to date, Bailey et al. documented a 10% mortality and 50% morbidity rate. Multivariate analysis revealed increasing age to be one of eight preoperative and intraoperative variables predictive of 30-day mortality [50].

In a retrospective cohort study analyzing outcomes from two large national databases, Finlayson and colleagues demonstrated higher mortality, lower 5-year survival, and greater probability of transfer to extended-care facilities among octogenarians undergoing esophagectomy for cancer when compared to patients aged 65–69 [51]. They identified similar results for patients undergoing pancreatectomy and lung resection for malignancy.

Finally, Ra and colleagues similarly analyzed the SEER-Medicare national database and found that age greater than 80, increasing Charlson comorbidity index, and operation at a low esophagectomy volume hospital were statistically significant predictors of postoperative mortality after esophagectomy for cancer [52].

The above-mentioned studies demonstrate well the ongoing controversy regarding postsurgical outcome in elderly esophageal cancer patients. Series of highly selected elderly patients at tertiary referral centers appear to demonstrate equivalent outcome when compared to younger patients. However, when national series are obtained from retrospective analyses of the VA and SEER-Medicare databases, increasing age appears to be an independent predictor of morbidity and mortality. It seems likely that the best possible surgical outcomes are obtained in elderly patients who are meticulously screened, medically optimized with regards to existing comorbidities, and undergo surgery in a high-volume tertiary referral center.

Neoadjuvant Therapy

The role of preoperative therapy followed by operation for Stage II and III disease remains ill-defined and hotly debated. The current information on neoadjuvant treatment can be divided into studies evaluating preoperative radiation, preoperative chemotherapy, and combined preoperative chemoradiation therapy. In operable patients with resectable tumors, the results of any preoperative therapy followed by resection must be compared with the results of primary resection alone. Importantly, this analysis must take into account the toxicities associated with

multimodality therapy and the impact on the intended resection and quality of life.

A number of randomized trials have failed to show any benefit from preoperative radiation therapy alone. Proponents of preoperative radiotherapy argue that the trials are too small to demonstrate the advantages of this approach. A meta-analysis of available randomized trials comprising 1,147 patients, however, found no improvement in survival with preoperative radiotherapy alone in patients with resectable esophageal cancer [53]. At this time, there is no indication for preoperative radiation therapy alone followed by resection.

The utility of preoperative chemotherapy alone is much more poorly defined. A large multicenter randomized trial in the USA (Intergroup Trial) of 440 patients failed to show any improvement in survival after three cycles of combined cisplatin and fluorouracil followed by surgery and two postoperative cycles when compared to surgery alone [54]. This is in contrast to a large randomized European study (Medical Research Council), which suggested that neoadjuvant chemotherapy resulted in nearly a 10% improvement in survival at 2 years [55]. Unfortunately, the preoperative staging techniques and duration of treatments were quite different, making the two studies difficult to compare. More recently, another European neoadjuvant chemotherapy trial (MAGIC trial) demonstrated improved survival with perioperative chemotherapy vs. surgery alone (36 vs. 23% at 5 years) [56]. Of note, 75% of the MAGIC trial participants had gastric cancer, while only 25% had either distal esophageal or GE junction adenocarcinoma. Also, only 41.6% of patients randomized to perioperative chemotherapy were able to complete all six prescribed cycles of therapy. In the most recent Cochrane Review of the topic, 11 randomized controlled trials with 2,051 patients suggested that preoperative chemotherapy plus surgery may offer a survival advantage compared to surgery alone for resectable esophageal cancer [57]. There was no demonstrable difference in the rate of resection, tumor recurrence, or postoperative morbidity. There was some chemotherapy-related morbidity. Presumably based on the relative success of the MRC and MAGIC trials, chemotherapy alone is utilized quite commonly as neoadjuvant therapy in Europe, while combined chemotherapy and radiation is utilized more commonly in the USA.

Several small randomized trials have evaluated combined preoperative chemoradiation followed by surgical resection. The most widely cited trial to justify the use of combined treatment followed by surgery was published by Walsh et al. in 1996 [58]. This study projected a 3-year survival of 32% in the neoadjuvant treatment group as compared to 6% in the surgery alone group for patients with adenocarcinoma. Critics were quick to point out the lack of appropriate staging, the poor survival in the surgical group as compared with other surgical series, and the small study size. A more recent study found equivalent median and 3-year survival in patients

with squamous cell carcinoma of the esophagus randomized to either preoperative chemoradiation followed by surgery or surgery alone [60]. An increased complication rate was noted in the patients undergoing preoperative chemoradiation therapy. A recent meta-analysis of ten randomized controlled trials of neoadjuvant chemoradiotherapy vs. surgery alone demonstrated an absolute survival advantage of 13% at 2 years favoring neoadjuvant therapy [60]. Despite a paucity of conclusive data, there seems to be an evolving consensus at most centers that patients with T3 and/or N1 disease should receive neoadjuvant chemoradiation. This issue remains unresolved, and operation remains the standard treatment for localized esophageal cancer outside of a clinical trial. At this time we consider neoadjuvant chemoradiotherapy to be investigational. Unfortunately, a large intergroup trial designed to answer this question was closed because of poor accrual.

Very little data exists regarding neoadjuvant chemoradiation in the elderly. Elderly patients are often not offered neoadjuvant therapy due to concerns of susceptibility to treatment-related toxicities. Moreover, octogenarians are often excluded from neoadjuvant trials. The M.D. Anderson Cancer Center group has reported their experience with combined modality therapy in elderly patients. They compared three groups of patients: (1) patients 70 years or older who received neoadjuvant chemoradiation; (2) patients younger than 70 who received neoadjuvant chemoradiation; and (3) patients 70 years or older who received surgery alone. Elderly patients receiving preoperative chemoradiation were more likely to require perioperative blood transfusions and had a higher incidence of postoperative atrial arrhythmias. Otherwise, postoperative outcome as well as median, 1-year, and 3-year survival were similar in the three groups [61].

Palliation

The goal of esophageal resection, whether as primary treatment or as part of a multimodality plan, is cure, though this goal remains elusive. Palliative esophagectomy is associated with mortality rates in excess of 20% and morbidity rates as high as 50% and should therefore be avoided [62]. Very effective palliation can be obtained with chemotherapy, radiation therapy, and endoscopic interventions such as stenting. The intent of palliation is to maintain comfort, restore swallowing function, and support nutrition. Establishment of alternative enteral access is helpful in maintaining nutritional status and hydration. When possible, this is provided by a percutaneous gastrostomy (PEG) tube placed under endoscopic guidance. For patients with bulky obstructing lesions who cannot undergo PEG, an open or laparoscopic gastrostomy or jejunostomy tube is required.

Radiation

Palliative radiotherapy relieves dysphagia in up to 75% of patients. The dose is 4,000–5,000 cGy delivered over 4 weeks. This allows patients with advanced disease and severe dysphagia to handle secretions and to swallow liquids as well as dietary supplements. Unfortunately, relief is not immediate and maximal improvement occurs at about 4 weeks following completion of treatment. In patients with a life expectancy greater than 3 months, combined chemotherapy with radiation is utilized. Short-term side effects from radiation therapy include skin irritation and erythema. Esophagitis with painful swallowing also occurs with some frequency. Additional complications include stricture formation, radiation pneumonitis, and fistulization to the airway.

Chemotherapy

Esophageal cancers are usually responsive to chemotherapeutic drugs, providing some palliation. Agents currently in use include fluorouracil and taxanes either alone or in combination with platin-based agents. Palliative chemotherapy requires time to effectively reduce symptoms of dysphagia and must be balanced with the associated risks of systemic treatment in usually debilitated, malnourished patients. Chemotherapy has been used in combination with radiation therapy with the goal of increasing response rates, lengthening the disease-free interval, and improving survival. The Radiation Therapy Oncology Group (RTOG) compared four cycles of cisplatinum+5-fluorouracil (5-FU)+50 Gy of radiation to radiotherapy alone with 64 Gy [63]. The trial was stopped early because the interim results demonstrated a significant survival advantage in the chemotherapy group, with median survival of 12.5 and 8.9 months and 2-year survival of 50 and 38% for the chemoradiation and radiotherapy groups, respectively. Therefore patients with locally advanced disease who are not considered surgical candidates as a result of unresectable tumors or medical risks should be considered for chemoradiation therapy rather than irradiation alone.

Endoscopic Palliation

Endoscopic techniques to restore luminal patency are palliative procedures that may be used in patients who are not candidates for primary surgical therapy, in an adjuvant setting for patients receiving combination therapy, or in the setting of locally recurrent cancer following surgery.

Endoscopic techniques include dilatation, thermal ablation with laser or coagulation probes, intubation with self-expanding stents, and photodynamic therapy (PDT). The variables that must be considered when selecting the specific method are cost, tumor location and length, whether the tumor is circumferential, and the presence or absence of an esophagorespiratory fistula.

Stenting

Palliative endoscopic intubation of inoperable malignant esophageal strictures was first described in the 1970s [64]. Currently, self-expanding coated and uncoated nitinol stents are utilized for palliation. These stents can be inserted either radiologically or endoscopically on an outpatient basis. Following insertion, the lumen can be balloon-dilated to an acceptable diameter to provide palliation. Cook and Dehn [65] cited four major benefits of covered expandable stent use: (1) shorter hospital stay compared with rigid tube insertion; (2) single hospital stay; (3) lack of readmission for recurrent obstruction from tumor ingrowth or food impaction; and (4) no procedure-related morbidity or mortality.

Neodymium:Yttrium–Aluminum–Garnet Laser Fulguration

Endoscopic neodymium:yttrium–aluminum–garnet (Nd:YAG) laser fulguration can be used to provide temporary relief of esophageal obstruction in patients with unresectable obstructing tumors. A flexible quartz fiber is passed through the working channel of the esophagoscope to deliver the laser energy at the fiber tip. Multiple sessions are usually required to achieve debulking and functional success. Laser fulguration is often combined with endoluminal stenting and radiation therapy. It can also be useful in patients who have undergone uncovered stenting procedures with ingrowth of tumor through the stent. To be a candidate for this therapy, the endoscope must be able to traverse the tumor. Contraindications for laser therapy include completely obstructing cancers and esophagorespiratory fistulae.

Photodynamic Therapy

Intraluminal PDT is a nonthermal ablative technique that can be used to palliate patients. This technique requires the systemic administration of a hematoporphyrin, which is

concentrated within the malignant cells. Approximately 48 h after administration of the photosensitizer, patients undergo endoscopy and an argon-pump dye-laser is used to deliver endoluminal light at a wavelength of 630 nm. This results in the generation of oxygen radicals, which quickly lead to tumor necrosis. The depth of penetration is relatively limited and this decreases the risk of full-thickness necrosis with perforation. Unfortunately, the photosensitizing agents are retained by the reticuloendothelial system in skin; thus, patients are sensitive to infrared wavelength light, including sunlight, radiant heat, fluorescent light, and strong incandescent light. Depending on the photosensitizing agent used, this sensitivity can persist up to 3 months, a challenging problem in patients with short life expectancies.

A recent series of 215 patients treated with palliative endoluminal PDT revealed a procedure-related mortality rate of 1.8%, effective palliation for patients with obstructing cancers in 85% of the treatment courses, and median survival of 4.8 months [66]. A number of patients in this series also required stenting, suggesting that PDT has a role in multimodal palliation of obstructing esophageal cancers.

Summary

- 16,470 Americans are diagnosed with and 14,280 die of esophageal cancer annually.
- Esophageal cancer is primarily a disease of the elderly. The median age at diagnosis for cancer of the esophagus is 69 years, with 61.5% of those diagnosed being age 65 or older.
- The incidence of esophageal adenocarcinoma has increased in the last 25 years greater than the incidence of any other major malignancy in the USA.
- Careful patient selection and medical optimization of existing comorbidities is of paramount importance in maintaining acceptable surgical outcomes, especially in the elderly.
- Despite a paucity of conclusive data, there seems to be an evolving consensus at most centers that patients with T3 and/or N1 disease should receive neoadjuvant chemoradiation.
- Whether postsurgical outcome in the elderly is worse than for younger patients remains controversial. It seems likely that the best possible surgical outcomes are obtained in elderly patients who are meticulously screened, medically optimized with regards to existing comorbidities, and undergo surgery in a high-volume tertiary referral center.
- Palliative esophagectomy is associated with mortality rates in excess of 20% and morbidity rates as high as 50% and should therefore be avoided. Very effective palliation can be obtained with chemotherapy, radiation therapy, and endoscopic interventions such as stenting.

Chapter 61

Benign Diseases of Stomach and Duodenum

Daniel Borja-Cacho and Selwyn M. Vickers

Normal Anatomy and Physiology of the Stomach

The stomach comprises five anatomical regions: the cardia, fundus, body or corpus, antrum, and pylorus. The cardia is contiguous to the lower esophageal sphincter and is the transition between the esophagus and the stomach. The cardia is used to create a reference horizontal plane that delimits the second and third regions of the stomach, the fundus, and corpus, respectively. The fundus is located above this horizontal plane. The body is delimited proximally by the horizontal plane at the level of the cardia and distally by the incisura angularis. The incisura angularis is located at the abrupt right angle created by the lesser curvature in the distal portion of the stomach; it marks the transition between the body and the antrum. The pylorus delimits the transition between the stomach and duodenum; it controls gastric emptying [1].

Microscopically, the stomach has four different layers. The external layer or serosa is an extension of the visceral peritoneum that covers the entire stomach. Underneath the serosa is the second layer known as muscularis propria which is formed by three different layers of muscle: an inner oblique layer, a middle circular layer and an outer longitudinal layer. The middle muscular layer forms the pylorus at the end of the stomach. The muscularis propria contains many ganglion cells that create a neuronal plexus known as myenteric or Auerbach's plexus. The third layer or submucosa is a firm matrix of collagen and elastin that contains plasma cells, lymphocytes, lymphatics, and blood vessels. Numerous ganglion cells are also located in this layer; they form the submucosal or Meissner's plexus. The gastric lumen is lined internally by the last layer or gastric mucosa which is formed by a columnar epithelium that covers a layer of connective tissue (lamina propria) and a thin muscular layer known as

muscularis mucosa. The columnar epithelium invaginates and contains different gastric pits. Each gastric pit opens to four or five different gastric glands [2].

Each region has a different function and histology, the whole surface of the stomach is lined with glands, but the epithelial cells that create these glands are different in each region. Gastric glands can be classified as oxyntic or antral based on the main type of cell present in them. Oxyntic glands are present in the proximal stomach (fundus and body) while antral glands are found in the distal stomach (antrum). Oxyntic glands produce pepsin and gastric acid. The major function of antral glands is to produce gastrin [3].

Mucous cells are the most common type of gastric cell and are present in the surface of the stomach. The mucous and bicarbonate secreted by them create a neutral mucous film that prevents back diffusion of hydrogen ions (H^+) from the gastric lumen to the cells. This film is very viscous owing to a high content of long chain oligosaccharides. Mucous cells also produce a hydrophobic film of phospholipids that blocks back diffusion of hydrogen ions [4].

The main component of oxyntic glands are parietal cells. These cells contain multiple mitochondria that generate the energy required for acid secretion. The apical membrane of parietal cells contains the H^+/K^+ -ATPase pump, responsible of gastric acid secretion. Parietal cells are mainly present in the proximal stomach (fundus and the body) [1].

Chief cells are located at the base of the oxyntic glands in the fundus and the body. They store pepsinogen inside intracytoplasmic granules that get secreted shortly after eating. This effect is mediated by acetylcholine. Pepsinogen is converted to pepsin in the gastric lumen; it breaks the ingested proteins into small peptides. Pepsin has an optimal activity at a pH 2.5, but if the intraluminal pH raises above 5, pepsin gets deactivated [5].

The body of the stomach also contains enterochromaffin like cells (ECL) that express histidine decarboxylase. ECL cells secrete histamine in response to acetylcholine release during the cephalic or vagal phase of gastric secretion. Histamine is also secreted in response to gastric distention. This effect is mediated by gastrin. Histamine induces the release of gastric acid by parietal cells [2].

SE, MMC 195, Minneapolis, MN 55455, USA
e-mail: vickers@umn.edu

G cells are the major component of antral glands. They secrete gastrin in response to gastric distention, vagal stimulation, or on increase of the intraluminal concentration of peptides and amino acids. Gastrin increases the secretion of gastric acid and pepsinogen. It also induces cell growth and differentiation of parietal cells.

D cells release somatostatin into the bloodstream when the concentration of gastric acid increases. The primary location of these cells is the antrum, but the body of the stomach also has D cells. Somatostatin inhibits the secretion of gastric acid, histamine, and gastrin [5].

Immature or undifferentiated cells are intercalated between other cells in the isthmus of gastric glands. They migrate and differentiate into other type of cells.

Effect of Age on Gastric Physiology

Gastric diseases are influenced by age. The surgeon caring for elderly patients has to understand that not only co-morbidities influence the clinical scenario; aging affects the normal physiology, histology, and pathology of the stomach.

The major changes in gastric physiology and histology associated with normal aging are:

1. *Gastric motility.* Aging is associated with normal gastric emptying of liquids but slower gastric emptying with solid foods. The accommodation reflex is slower in elderly patients. In healthy subjects the presence of nutrients in the small intestine decreases antral contractions, increases the pyloric tone, and induces relaxation of the gastric fundus. These responses are mediated by different hormones but cholecystokinin (CCK) is most responsible for this response. The plasma concentrations of CCK are persistently elevated in older patients before and after meals. As a consequence, they experience decreased appetite and slower gastric emptying [6]. The decrease in gastric motility can influence drug absorption. This is one of the

reasons why older patients have more side effects as compared to younger patients [7].

2. *Bicarbonate secretion.* Aging decreases both the basal and induced secretion of bicarbonate in the human stomach which decreases acid neutralization in elderly patients [6].
3. *Mucous.* The quality of the mucus in the stomach decreases with age; this effect is independent of *Helicobacter pylori* infection and any medication. In vivo studies with rats have shown that the population of mucous cells decreases in older animals. In humans, the total number of mucous secreting cells only decreases after *H. pylori* infection [7].
4. *Prostaglandins (PG) synthesis.* The main types of PGs identified in the gastric mucosa are PGE2 and PGI2 and lesser amounts of PGF2 and PGD2 [4]. Mucous cells release PGE2 and PGI2 on epithelial injury. Both molecules increase the mucosal blood flow and induce the release of mucous and bicarbonate secretion. The mucous and bicarbonate create a preepithelial barrier that keeps the pH neutral [5]. Gastric biopsies from elderly patients showed a decrease in PGE2 and PGF2 α levels [8]. Studies in rats have shown that the constitutive expression of COX (COX-1), the enzyme that catalyzes the conversion of arachidonic acid to PGs decreases in older animals. This finding has yet to be confirmed in humans [9].
5. *Pepsin.* Studies evaluating the secretory function of the stomach have indicated that pepsin secretion decreases in elderly subjects [9].
6. *Mucosal blood flow.* There is no evidence that mucosal blood flow changes in older healthy patients [9].
7. *Gastric acid secretion.* Studies prior to 1983 demonstrated that gastric acid secretion decreases in elderly patients. However these studies were completed before *H. pylori* was identified. The prevalence of *H. pylori* infection increases with age (up to 80% in patients older than 80 years). Chronic infection with *H. pylori* induces atrophic gastritis, therefore the hypochlorhydria previously described in older patients is a consequence of *H. pylori* infection, not a consequence of aging. Current evidence suggests that gastric acid secretion is not influenced by aging [10].

CASE STUDY

A 77-year-old white female arrives to the emergency department complaining of 3 days with multiple episodes of melena and seven episodes of hematemesis during the last day. She denies any other symptom. Her family affirms that she has longstanding diabetes mellitus complicated with renal insufficiency and coronary artery disease that required treatment with two stents 3 years ago. She also had total right knee replacement 6 months ago. Her current medications are insulin, lisinopril, ibuprofen, and clopidogrel.

She appears initially stable, with normal vital signs, no acute distress but while being examined she has an episode of massive hematemesis. The heart rate increases to 120 bpm, blood pressure decreases to 70/50, respiratory rate 20, the saturation decreases to 85%.

1. What is the initial management required by this patient?

At an upper endoscopy a 2-cm ulcer is seen in the duodenum. Bleeding is successfully controlled and remains hemodynamically stable; however, 10 h later

(continued)

CASE STUDY (continued)

she develops a new episode of hematemesis with hypotension and tachycardia.

2. What treatment should be offered to this patient now?

- (a) Repeat upper endoscopy
- (b) Emergent laparotomy

The bleeding continues and the patient is taken to the OR.

3. Where is the most common location of duodenal ulcers that require surgery?

The patient recovers successfully after surgery; however, she is concerned about continuing treatment with clopidogrel and ibuprofen.

4. What is the medical treatment required by this patient?

Peptic Ulcer Disease

Epidemiology

The number of admissions, surgeries, and mortalities related to peptic ulcer disease (PUD) has generally decreased; however, the proportion of patients older than 65 years admitted for duodenal or gastric ulcer complications is increasing [11]. The first clinical manifestation of PUD is an acute abdomen in up to 50% of elderly patients [12]. Acute upper gastrointestinal (GI) bleeding related to PUD is more frequent in elderly patients [13, 14].

Physiopathology

In the early 1900s, Schwarz dictated: “no acid, no ulcer”; however, the advances in gastric physiology during the past 40 years now establish that PUD results from multiple factors that either injure the mucosal barrier in the stomach and duodenum or increase the production of gastric acid. In the healthy gastric mucosa the mucous and bicarbonate form a hydrophobic preepithelial barrier that prevents backflow of H^+ and maintains a neutral pH even if the intraluminal concentration of gastric acid is increased [5]. Mucosal injury occurs regularly but secondary components of the mucosal defense repair it. Elderly cells in the gastric mucosa are replaced continuously; the epithelium is renewed every 2–4 days. The normal response after epithelium damage is migration of healthy cells from the gastric pits to denude areas of the basement membrane, increase in the release of mucous by damaged cells, and the release of plasma by the mucosal vessels. When mucous and plasma mix, they create a mucoid cap that protects the denuded area. Although the basement membrane is highly sensitive to gastric acid, the mucoid cap prevents further damage because it has a neutral pH. This response is dependent on mucosal blood flow. Sensory afferent nerve endings in the mucosa release calcitonin gene-related peptide (CGRP) if the gastric mucosa gets exposed to gastric acid. CGRP vasodilates mucosal vessels. The increase

in blood flow is mediated by nitric oxide. The enhanced blood flow buffers, dilutes, and removes gastric acid. PGs are crucial for this defense because they induce the release of mucous, bicarbonate, and phospholipids from the mucous cells. PGE2 and PGI2 also increase blood flow to the gastric mucosa [4]. True ulcers occur if the insult continues and extends into the muscularis propria.

Classification of Gastric Ulcers

Gastric ulcers are classified according to location and possible physiopathology in four types: Type I are gastric ulcers located in the lesser curvature; Type II are gastric ulcers associated with a history of previous or active duodenal ulcer; Type III are prepyloric ulcers; Type IV are ulcers located near the GE junction. While Type II and III are associated with increased acid production, Type I and IV are associated either with malignancy or decreased mucosal defense [15].

Etiology

The main factors that predispose to PUD are as follows:

Helicobacter pylori

This microaerophilic gram-negative spiral bacterium colonizes the preepithelial mucous layer of the stomach. It is one of the most common human chronic infections worldwide; humans are the only known reservoir for *H. pylori*. The transmission is either fecal–oral or oral–oral. Prevalence is influenced by socioeconomic status, ethnicity, and age. Around 30–40% of the US population is infected with *H. pylori* (50% African Americans, 60% Mexican Americans, 26% in Caucasians) [16, 17]. Approximately 50% of the world’s population is infected; the frequency is higher in developing countries with poor sanitation and household hygiene, and

with low family income and educational level. The infection is acquired during childhood in developing countries. In high-income countries, the rate of seroconversion is approximately 0.5–1% per annum. In the USA, the prevalence increases with age: less than 10% before 30 years, 50% around 50 years, and up to 80% in patients older than 80 years [7, 11, 18]. *H. pylori* always produces inflammation (gastritis) but only 15% of the patients develop PUD [16]. *H. pylori* secretes urease, which produces ammonium, that favors gastric colonization with *H. pylori* and damages epithelial cells. *H. pylori* also produces proteases and phospholipases that affect the efficacy of the mucous-bicarbonate layer. *H. pylori* has a rich catalase activity that blocks the neutrophil response [19]. These bacteria also release toxins that generate a chronic inflammatory response which results in type B atrophic gastritis.

Why *H. pylori* induces duodenal inflammation is not fully understood. Some studies suggest that gastric metaplasia in the first portion of the duodenum facilitates *H. pylori* colonization and further inflammation. Other studies posit that antral *H. pylori* infection increases gastric acid secretion because the ammonia produced by *H. pylori* increases the pH to which G cells are exposed and because the population of the D cells decreases with *H. pylori* infection. Duodenal *H. pylori* infection decreases bicarbonate secretion in the duodenal cells [16, 19].

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

At least 40% of the patients older than 65 years use NSAIDs. Between 1 and 8% of these patients will require a hospitalization to treat a NSAID-related complication. Duodenal and gastric ulcers develop in 5–8% and 15–20% of patients taking NSAIDs, respectively. Proton pump inhibitors (PPI) or misoprostol decrease the risk of PUD but only 10–20% of the patients receive prophylaxis [13]. The risk of NSAIDs' toxicity increases with age; the risk of serious GI complications after 1 year of NSAIDs ingestion is 0.32% in patients older than 65 as compared to 0.039% in younger patients [20]. NSAIDs significantly decrease the production of mucous, bicarbonate, and phospholipids in the stomach and duodenum because these drugs inhibit the activity of COX-1 and COX-2. The final result is a preepithelial barrier that cannot prevent H⁺ backflow.

NSAIDs also delay mucosal healing because they decrease PG synthesis, therefore the mucoid cap cannot be formed, and the increase in mucosal flow and mucosal regeneration cannot occur. COX-1 inhibition also releases endothelin-1, a potent vasoconstrictor, and for that reason blood flow to the mucosa decreases in patients with mucosal injury induced by NSAIDs [20]. NSAIDs also increase the expression of leukocyte adhesion molecules and neutrophil

adherence. Neutrophils cause further damage because they release proteases and reactive oxygen metabolites [4].

The toxic effects of NSAIDs are mainly systemic but these drugs also induce topical cytotoxic injury in the gastric mucosa because they increase cellular permeability with diffusion of the drugs to mucosal cells [4].

NSAIDs ingestion and *H. pylori* infection are independent risk factors for PUD, but if both factors coexist the risk of PUD is synergistically increased [21]. This is particularly likely in elderly patients because both risk factors are more prevalent in older populations [11].

Zollinger–Ellison Syndrome

This syndrome is associated with neuroendocrine tumors that secrete excessive amounts of gastrin into the bloodstream. Gastric acid greatly increases in these patients. Zollinger–Ellison syndrome (ZE syndrome) accounts for 0.1–1% of all peptic ulcers. The diagnosis requires an elevated gastrin (>500 pg/ml) in the presence of an acid gastric pH (pH < 5). In patients with nondiagnostic gastric elevations (>150 but less than 500 pg/ml) a rise of more than 120 pg/ml after the intravenous administration of secretin (0.2 µg/kg) is diagnostic. The tumor can be localized with CT, MRI, endoscopic ultrasound, selective arterial secretin stimulation test, and somatostatin receptor scintigraphy but surgical exploration of the gastrinoma triangle with intraoperative ultrasound is the best method to localize the tumor. This entity is more common in young patients (mean age 41) but it should be considered in patients with atypical PUD localization (ulcers in the second, third, or fourth portion of the duodenum, jejunum), severe gastroesophageal reflux, diarrhea, PUD refractory to treatment and recurrent disease in patients without *H. pylori* infection or NSAID ingestion [22, 23].

Smoking

Smoking decreases wound-healing, increases the risk of *H. pylori* infection and is an independent risk factor that predicts failure to antibiotic treatment [24].

Clinical Manifestations of Noncomplicated Peptic Ulcer Disease

The cardinal symptom is epigastric pain without any irradiation. This pain is frequently described as “burning,” “gnawing,” or “hunger pain.” It is usually exacerbated with fasting and relieved with the ingestion of food or anti-acids. The presence of other symptom than pain such as weight loss,

anorexia, melena, hematemesis, constant pain or pain irradiated to the back suggests complicated PUD. Differential diagnosis includes dyspepsia, upper GI malignancies, cholelithiasis, pancreatitis, and GERD.

Elderly patients always require an extensive workup because the risk of malignancy increases with age. The conservative approach recommended for young patients without complications is not recommended for elderly patients. The gold standard test to diagnose PUD is an upper endoscopy. Duodenal ulcers typically occur in the first portion of the duodenum; they are usually not associated with malignancy (risk less than 1%). The presence of multiple ulcers or ulcers located beyond the second portion of the duodenum suggests ZE syndrome. Gastric adenocarcinoma exists in up to 5% of the patients with gastric ulcers with gross benign appearance, therefore all gastric ulcers should be biopsied [15].

Medical Treatment for Noncomplicated Peptic Ulcer Disease

The mainstay of treatment is to inhibit gastric acid secretion. This can be achieved with proton pump inhibitors (PPIs) or with Histamine-2 receptor antagonists (H2RA). PPIs are irreversible inhibitors of the H⁺/K⁺-ATPase. They should be given before meals. The recommended therapy for duodenal ulcers is 4–6 weeks, the healing rate is between 80 and 100%, for gastric ulcers the recommended therapy is 8 weeks, and the healing rate is 70 and 85%. In case the ulcer is associated to hypergastrinemia or NSAIDs ingestion, the treatment should be continued. H2RA are reversible inhibitors of the H2 receptor in the membrane of parietal cells. The healing rate is 70–80% in duodenal ulcers and 55–65% in gastric ulcers. The duration of treatment is the same than PPIs [5]. An alternative in the treatment of PUD is sucralfate, this agent improves mucosal healing because it creates a protective barrier in the ulcer, stimulates bicarbonate, mucous, and growth factor release. Misoprostol is a PG analogue that improves ulcer healing; however, it is frequently associated to GI side effects such as diarrhea.

The presence of *H. pylori* infection is associated with a high recurrence rate; in duodenal ulcers the recurrence rate is 95% without *H. pylori* eradication compared to 12% for those patients who receive eradication treatment. The recurrence rate for gastric ulcers without *H. pylori* eradication is 74% vs. 13% after eradication [19]. The two most common techniques to diagnose *H. pylori* infection are urea breath test or detection in the biopsy; other tools are rapid urease testing, culture, polymerase chain reaction, antibody testing, and the fecal antigen test. Eradication treatment is always indicated in patients with PUD complicated or uncomplicated. The current regimens

TABLE 61.1 FDA approved regimens for *Helicobacter pylori* eradication*

Regimen	Duration (days)
1. Omeprazole 20 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
2. Lansoprazole 30 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
3. Esomeprazole 40 mg q.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	10
4. Rabeprazole 20 mg b.i.d. + Clarithromycin 500 mg b.i.d. + Amoxicillin 1 g b.i.d.	7
5. Bismuth 525 mg q.i.d. + Metronidazole 250 mg q.i.d. + Tetracycline 500 mg q.i.d. + Histamine-2 Receptor Antagonists**	14

*The success rate is around 80%

**In this regimen the total duration of Histamine-2 receptor antagonists therapy is 4 weeks

approved by the FDA for the eradication of *H. pylori* are in Table 61.1. The success rate is approximately 80% [16, 17].

Patients with gastric or duodenal ulcers associated with NSAIDs require replacement of the NSAIDs with narcotics or acetaminophen plus the administration of a PPI. Prophylaxis with misoprostol or PPIs is indicated in elderly patients that cannot stop NSAIDs. The incidence of ulceration decreases from 20 to 4.5% [4].

Clinical Manifestations of Complicated Peptic Ulcer Disease

The first clinical manifestation is a complication in 50–60% of elderly patients[20]. Elderly patients frequently have comorbidities that affect the mental status or pain perception (uncompensated diabetes, stroke, dementia) or they are receiving drugs that create or mask PUD (i.e., NSAIDs, narcotics, steroids). The diagnosis is frequently challenging because the normal systemic inflammatory response (fever, leukocytosis) is often absent in elderly patients or is affected by drugs (steroids, beta blockers) [12, 14].

PPI, H2RA, and antibiotic therapy for *H. pylori* have decreased the number of elective surgical procedures required for PUD, but the incidence of complications such as perforation or bleeding has not changed significantly over time.

Perforation

The incidence of perforation in PUD has remained stable or slightly increased in elderly patients, especially women [25]. Between 2 and 10% of the patients with duodenal ulcers present as a perforated ulcer.

Elderly patients frequently present to the emergency room without any history of PUD. The diagnosis is suggested by

acute epigastric pain that rapidly becomes generalized. The patient is often diaphoretic and tachycardic; low grade fever can also occur. The presence of generalized tenderness, positive rebound, and abolished peristalsis is usually evident, but the physical examination in very old or immunocompromised patients can be nonspecific. The diagnosis is confirmed with chest radiography because 70 and 80% of the patients have free subdiaphragmatic air. If the physical examination is nonconclusive or in the absence of free air the most useful test is a CT scan of the abdomen and pelvis; this study excludes other diagnosis and is highly sensitive to detect free intra-abdominal air.

Despite conservative treatment with antibiotics and IV fluids has been described in hemodynamically stable patients with contained perforations, elderly patients usually require surgical treatment. After the initial evaluation, an aggressive IV fluid resuscitation is crucial. Elderly patients frequently have cardiovascular comorbidities that require measurement of central venous pressure (CVP) and urine output. Broad spectrum antibiotics should be started on diagnosis. The initial assessment and medical therapy should not delay surgery. The most frequent surgical procedure for perforated ulcers is primary closure plus reinforcement with an omental patch. The treatment for perforated ulcers is summarized in Fig. 61.1.

Primary Closure Reinforced with Omental Patch

The patient is placed in supine position; under general anesthesia an endotracheal and nasogastric tube, and a Foley catheter are placed. Our preferred approach is a mid-line supraumbilical incision because it provides easy access to the stomach and duodenum; in case a different pathology is found the incision can be easily extended. After an exploratory laparotomy has ruled out other diagnoses, the gastrocolic ligament is divided to enter the lesser sac. This maneuver allows a complete visualization of the anterior and posterior surfaces of the stomach. If the perforation is in the stomach, the margins of the perforation are debrided (Fig. 61.2). Ulcer biopsies must be sent for definitive diagnosis because gastric cancer can simulate perforated PUD. The defect is closed with a full-thickness single layer of interrupted 3-0 silk stitches (Fig. 61.3). The primary closure is reinforced with omentum (Omental patch) (Fig. 61.4). The tails of the sutures are used to hold the omental pedicle, avoiding ischemia while the sutures are tied (Fig. 61.5). It is important to avoid vascular injury to the omentum during dissection of the gastrocolic ligament. The abdominal cavity is copiously irrigated. The fascia is closed with a running suture. The subcutaneous tissue is also irrigated. The skin is usually not closed due to high risk of infection.

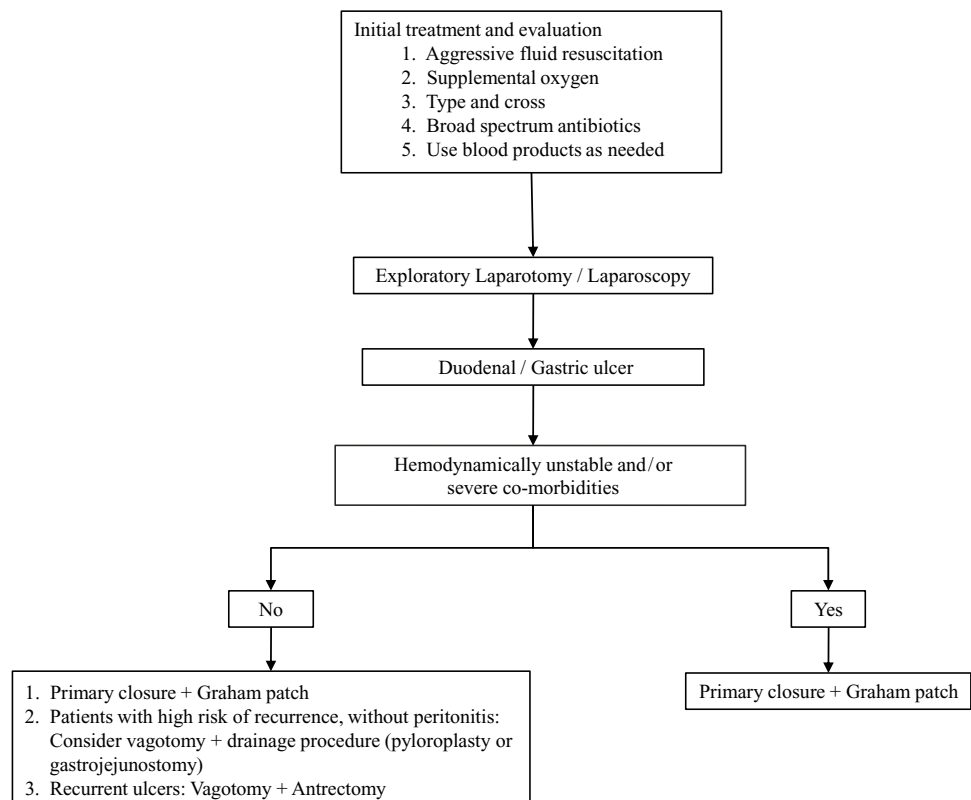

FIGURE 61.1 Algorithm for the management of perforated peptic ulcers in elderly patients.

FIGURE 61.2 Debridement of the ulcer margins.

FIGURE 61.3 Primary closure of a perforated ulcer.

FIGURE 61.4 Reinforcement of the primary closure using an omental patch.

FIGURE 61.5 Final view of the primary repair of a perforated ulcer with an omental patch.

For duodenal ulcers, after a complete exploratory laparotomy is done, the duodenum is mobilized anteriorly and medially (Kocher maneuver). This maneuver avoids excessive tension on the primary closure. Both the anterior and posterior surfaces are carefully inspected. Routine biopsies are not required because the risk of malignancy in duodenal ulcers is very low; however, adequate debridement of the margins is required. The duodenal defect is closed following the same principles for a gastric ulcer: interrupted full-thickness sutures reinforced with an omental patch. Duodenal ulcers are associated with more inflammation and defects larger than gastric ulcers, so if the primary closure is not possible, a true omental patch (Graham patch) is used. In this repair the ulcer margins are not approximated, the orifice is only plugged with omentum sutured to the duodenal defect, avoiding ischemia in the omentum. The abdominal cavity is closed following the same principles described for gastric ulcers. Patients are usually extubated unless they have persistent hemodynamic instability and/or if the patient has any oxygenation problem. The nasogastric tube is kept to prevent gastric or duodenal distention and it is pulled out once the bowel function is normal. The integrity of the repair is evaluated with an upper GI study done with hydrosoluble contrast.

Additional procedures that decrease gastric acid secretion are not recommended because elderly patients frequently present with shock and severe co-morbidities that require a rapid intervention to control the damage. Often, these patients have a delay in diagnosis and generalized peritonitis is found during the laparotomy, therefore further dissection of the hiatus increases the risk of other complications such as mediastinitis. It is important to consider also that PPIs and *H. pylori* eradication treatment decrease the risk of recurrence.

The morbidity and mortality associated with perforated PUD are between 25–89% and 4–30%, respectively. Risk factors associated with increased morbidity and mortality are age, delay in diagnosis, high ASA score (III and IV), and shock during surgery. Age is crucial because patients older than 65 years have a mortality rate of 37.7% as compared with 1.4% in younger patients. A delay in diagnosis (>24 h) increases the mortality rate in elderly patients. The most common causes of mortality are myocardial infarct, arrhythmias, septic shock, and pneumonia. Resection procedures (i.e., antrectomy) are also associated with more mortality than primary closure in these patients [26].

Bleeding

Bleeding is the most common complication of PUD, which in turn is the most common source of upper GI bleeding. It is seen in 15–20% of the patients [27, 28]. The frequency of acute upper GI bleeding has decreased in general but the proportion of patients older than 60 years that bleed is increasing; recent studies have published that 65 and 25% of the patients are older than 65 and 80 years old, respectively [13, 14]. This trend is a result of increased life expectancy: older patients have more co-morbidities that predispose them to PUD (i.e., chronic renal failure, myeloproliferative disorders, portal hypertension) or that require anticoagulation. Elderly patients ingest more NSAIDs either as analgesics or as a preventive measure for other disorders.

The most important risk factor to develop GI bleeding is NSAIDs ingestion. These drugs decrease the mucosal defense to gastric acid and inhibit platelet aggregation by decreasing thromboxane A₂ production. The risk is dose dependent, but bleeding occurs also with low aspirin doses (75–325 mg/day) [29]. The risk of bleeding is considerably lower with COX-2 inhibitors as compared with nonselective NSAIDs, but COX-2 inhibitors can induce bleeding when they are combined with anticoagulants, aspirin, or any other NSAIDs [27]. The risk of bleeding significantly increases in patients taking anticoagulants, serotonin reuptake inhibitors, or drugs that prevent platelet aggregation [20]. *H. pylori* infection marginally increases the risk of bleeding; however, concomitant NSAIDs use and *H. pylori* infection significantly increase the risk of bleeding [21].

The main symptom is melena and/or hematochezia. The main focus during the initial evaluation is to assess the hemodynamic status. The presence of tachycardia, systolic blood pressure <100 mmHg, postural hypotension or altered mental status suggests a significant blood loss so an aggressive fluid resuscitation should start immediately. The initial goals of resuscitation are to establish a secure airway if needed, to ensure proper breathing, and to administer IV fluids. Fluid resuscitation is challenging in elderly patients with preexistent cardiac or renal failure; the placement of a central line

and Foley catheter is particularly useful but should not delay further treatment. It is mandatory to obtain a complete blood count, glucose, blood urea nitrogen, creatinine, electrolytes, INR, type and cross-match in all patients. The use of blood products needs to be individualized for each patient; any history of coronary artery disease lowers the threshold for packed red blood cells. Plasma should be given to any patient with a coagulopathy associated with drugs or co-morbidities. Once the patient is hemodynamically stable, he or she should be thoroughly examined. In the absence of any other disease the physical examination of the abdomen is usually unremarkable.

Upper GI endoscopy is the gold standard for diagnosis and initial therapy because it indicates the source of the bleeding, rules out other diagnoses, and because bleeding can be stopped using hemoclips, sclerosing agents, epinephrine, thrombin or fibrin glue, or thermal contact with bipolar electrocoagulation, heater probe or argon plasma. Except for epinephrine, all these techniques can be used either to stop active bleeding or to prevent it in visible vessels. Epinephrine injection can partially control the bleeding before implementation of other techniques. Endoscopic therapy has a low complication rate (0.5%) [30]. The two most common complications are perforation or induced bleeding.

Most duodenal ulcers that bleed are in the posterior wall of the first portion of the duodenum; the bleeding almost always arises from the gastroduodenal artery (GDA) [11]. The most common vessels that bleed in the stomach branch off the inferior branch of the left gastric artery in the lesser curvature [15].

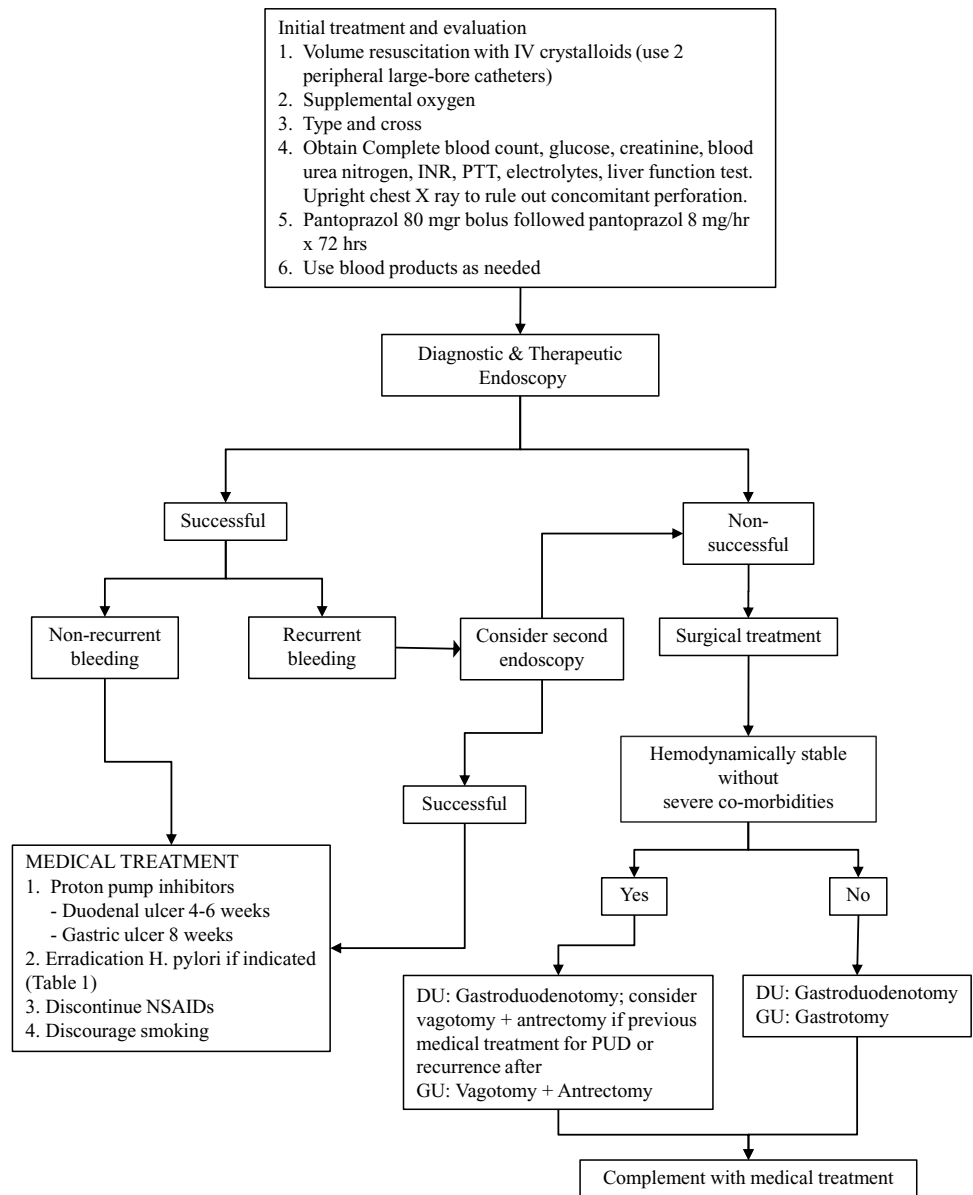

Approximately 20% of the patients will rebleed after endoscopy. For these patients, a second endoscopy is indicated because the success rate is high without significant morbidity; however, if bleeding persists, surgery is necessary. The frequency of surgery depends on the endoscopist's experience; the failure rate in high volume centers is less than 3%; however, most centers report a failure rate between 5 and 10–20% [14, 15, 19].

Another indication for surgery is a persistent blood requirement, if more than 4 units are given during 24 h. Because elderly patients develop coagulopathy associated to active bleeding faster than younger patients and active bleeding aggravates preexistent co-morbidities (myocardial infarct, renal failure, and stroke) faster than in younger patients, surgery needs to be considered in elderly patients before 4 units of blood are required.

Ulcer size is not considered a surgical indication but ulcers bigger than 2 cm are associated with greater risk of rebleeding. If an ulcer >2 cm presents with persistent hypotension, surgical treatment should be considered [14].

Adequate platelet aggregation and hemostasis require an intragastric pH>6. Different studies have shown that high doses of PPI decrease the re-bleeding rate by 54% and the need for surgery by 41%. The recommended regimens are

FIGURE 61.6 Algorithm for the management of acute peptic ulcer bleeding in elderly patients.

pantoprazol 80 mg IV bolus followed by 8 mg/h for 3 days; pantoprazol 80 mg bolus followed by pantoprazol 40 mg every 12 h [31]. Figure 61.6 summarizes the diagnosis and treatment of bleeding ulcers.

Surgical Treatment of Bleeding Duodenal Ulcers

The anesthesia, positioning, and incision are the same as perforated ulcers. A full Kocher maneuver follows an exploratory laparotomy. Profuse bleeding in the first portion of the duodenum can be partially stopped by compressing the duodenal bulb. The pylorus is identified by the palpation of the concentric ring between the stomach and the duodenum, or by visual identification of the pyloric vein that crosses

anterior to the pylorus (Mayo's vein). Two 3-0 silk sutures are placed in the superior and inferior borders of the anterior surface of the pylorus. A 3-cm longitudinal gastrotomy perpendicular to the pylorus is followed by 3-cm extension toward the duodenum. The most common bleeding vessel is the GDA, which is located in the posterior duodenal wall (Fig. 61.7). Three stitches are placed to stop bleeding: two initial figure 8 stitches in the superior and inferior margin of the ulcer followed by a third figure 8 or U-stitch that controls the pancreatic branch of the GDA (Fig. 61.8). Each suture must be placed carefully to avoid injury to the common bile duct. Once vascular control is achieved, the duodenum and stomach are carefully inspected to rule out any other source of bleeding. The aperture is closed transversely. The internal layer is a full-thickness continuous closure with an absorbable

FIGURE 61.7 Bleeding ulcer in the posterior wall of the first portion of the duodenum.

FIGURE 61.9 Primary closure of the duodenotomy.

FIGURE 61.8 Haemostasis of the GDA using 3-0 silk stitches.

3-0 suture reinforced by a second layer of interrupted seromuscular stitches using 3-0 silk (Lembert type) (Fig. 61.9). The closure can be reinforced with omentum, similar to a Graham patch.

Additional procedures that decrease acid secretion are controversial. The recurrence rate was high before predisposing risk factors to develop PUD were fully understood. Not all patients require anti-acid procedures; the surgeon has

to consider additional interventions based on other factors. The most important factor is the patient's hemodynamic condition. In case of patients with severe co-morbidities or refractory shock the only aim of surgery is to stop the bleeding. Additional factors to be considered are NSAIDs use, *H. pylori* infection, and previous surgical or medical treatment for PUD. Two randomized trials have shown that eradicating *H. pylori* decreases bleeding recurrence after 1 year of follow-up [32, 33]. In patients without history of PUD or *H. pylori* infection, we recommend only to control the bleeding. In stable patients with previous medical or surgical PUD treatment or who require NSAIDs, a truncal vagotomy with or without antrectomy should be considered. These procedures will be described in the treatment of bleeding gastric ulcers. The postoperative management is the same as described for the perforated ulcers.

Surgical Treatment of Bleeding Gastric Ulcers

Most gastric ulcers that bleed are type I. The anesthesia, patient's position, and incision are similar to duodenal bleeding ulcers. Treatment depends on the hemodynamic status of the patient. For those with shock, a conservative approach that only aims to control bleeding is recommended. Through an anterior gastrotomy, the ulcer is biopsied and oversown with figure 8 stitches. The gastrotomy is closed in two layers using the same technique described for closing bleeding duodenal ulcers.

Stable patients are treated with truncal vagotomy plus an antrectomy. The gastrocolic ligament is divided to enter the

lesser sac; this dissection begins in the middle point between the pylorus and the cardia and continued distally to the pylorus where the right gastroepiploic vessels are transected. Adhesions between the posterior gastric wall and the pancreas are divided. The gastrohepatic ligament is divided in order to control the inferior branch of the left gastric artery. The proximal and distal margins of this dissection are the incisura angularis and the beginning of the first portion of the duodenum, respectively. The stomach is divided proximally with a gastrointestinal anastomosis (GIA) stapler. The first portion of the duodenum is divided immediately after the pylorus with a transverse anastomosis (TA) stapler. The integrity can be restored with a Billroth I, Billroth II, or a Roux en Y gastrojejunostomy.

The first option to reconstruct is a gastroduodenostomy, or Billroth I, which requires a complete Kocher maneuver to avoid tension in the anastomosis. The duodenum is mobilized close to the gastric remnant. The anastomosis is done in two layers. The internal layer is a continuous full-thickness layer using a 3-0 absorbable suture reinforced by a second layer of interrupted seromuscular sutures with 3-0 silk (Lembert type). This anastomosis is considered the most physiological reconstruction as the normal transit of the stomach goes to the duodenum; however, alkaline gastritis can occur. Previous scarring can limit the Kocher maneuver and the anastomosis cannot be done without tension.

The second reconstruction is a Billroth II procedure or gastrojejunostomy, which is preferred in cases with excessive scarring that prevents duodenal mobilization. This side-to-side anastomosis is created between the posterior gastric wall and the anti-mesenteric border of a jejunal limb (10–20 cm distal to Treitz ligament). The jejunum is brought close to the stomach, anterior or posterior to the transverse colon (antecolic or retrocolic, respectively). There is no functional difference in benign diseases. The anastomosis is done with a stapler or manually using the Hofmeister technique. The anastomosis is stapled through a small gastrotomy and enterostomy. The stapler is introduced through these defects, and the anastomosis is created. Both orifices are closed manually with a continuous full-thickness layer reinforced by an interrupted seromuscular layer. The mesenteric defect in the mesocolon is closed with interrupted 3-0 silk stitches in order to avoid internal hernias. The two most common options to restore are Billroth I or II, but both anastomoses predispose patients to alkaline gastritis or reflux; therefore, some surgeons recommend a reconstruction using a Roux en Y gastrojejunostomy for benign conditions.

A truncal vagotomy follows the anastomosis. This step requires mobilization of 4–5 cm of the intra-abdominal esophagus. The initial step is liver mobilization; the falciform ligament is followed posteriorly until the left triangular ligament can be identified and sectioned. Right traction of segments II and III of the liver allows direct visualization of the cardia. The proximal

gastrohepatic ligament is divided, and dissection is continued proximally until the phreno-esophageal membrane is identified and sectioned; this allows the right wall of the esophagus to be visualized. The division continues proximally 4–5 cm; the peritoneum is then transected transversally and continued through the left border of the esophagus which has to be mobilized also 4–5 cm. This dissection is done carefully to avoid any splenic injury or bleeding from the short gastric vessels. The placement of a Penrose drain around the esophagus facilitates exposure. The left vagus nerve is easily identified if the esophagus is retracted posteriorly and inferiorly. At least 2 cm of nerve are clipped and divided. The right vagus, in the posterior wall, is located if the esophagus is retracted inferiorly and to the left. At least 2 cm are divided. Both nerves are sent to pathology to confirm the vagotomy. Once the dissection is completed the abdomen is closed using a standard technique. Postoperative management is similar to duodenal bleeding ulcers.

Outcome

This complication has a mortality rate that ranges between 10 and 35% in patients older than 60 years as compared with 10% in younger patients. Bleeding is the most common complication that causes death in PUD. Risk factors that predict high mortality are increased age, severe co-morbidities associated, re-bleeding, or patients that present with hypotension, shock, or in-hospital bleeding [11, 13, 15].

Gastric Outlet Obstruction

Gastric outlet obstruction (GOO) is the final result of chronic edema, scarring, and fibrosis of the distal stomach or duodenum. The area proximal to the stenosis is chronically dilated; gastric dilation induces gastrin release, which is further aggravating because it increases gastric acid production. The incidence of GOO has declined with the advances in the medical therapy for PUD. GOO accounts for less than 5–8% of all PUD complications. The typical symptoms are early satiety, nausea, vomit of undigested food, heartburn, and weight loss.

The most common GOO etiology is malignancy (60–80%), therefore multiple biopsies from the stenosis need to be taken [34]. Only 5–8% of patients with GOO have PUD [28]. Other diagnoses to consider are external duodenal or gastric compression (i.e. pancreatic pseudocysts, tumors), GOO caused by a large gallstone (Bouveret syndrome), bezoars, and gastroparesis. The initial evaluation relies on an upper endoscopy with multiple biopsies plus a hydrosoluble-contrast upper GI series; however, if external compression is suspected, a CT scan is required.

The initial treatment is conservative and uses an NG tube to decompress the stomach, IV infusion of PPIs, and corrects any

electrolyte or acid–base disorder. Prokinetics are contraindicated. If *H. pylori* infection is proven, antibiotic therapy is indicated because some studies report that symptoms improve after *H. pylori* eradication [34]. Nutritional status is crucial; a liquid diet should be attempted unless the patient cannot tolerate ingestion. Severe GOO requires total parenteral nutrition. Medical treatment improves GOO obstruction in 50% of the patients [35]. Endoscopic therapy with endoscopic balloons increases the success rate up to 70% [36, 37]. Serial dilations can be attempted in patients with recurrent stenosis, but the failure rate is proportional to the number of dilations attempted. The most common complication is perforation. Although our experience with endoscopic stenting for malignancies is increasing, current data on benign disease is limited [38].

Elderly patients benefit from conservative therapy because they have multiple co-morbidities; however, in refractory cases a truncal vagotomy plus antrectomy may be necessary. Chronic gastric obstruction dilates the stomach with subsequent accumulation of food and secretions; this condition predisposes patients to aspiration pneumonia, and wound infection due to bacterial overgrowth, so decompressing stomach with an NG tube is indicated before surgery. The technique for truncal vagotomy plus antrectomy is the same as described previously. Prolonged gastric dilation increases the risk of delayed gastric emptying which can be aggravated by narcotics or co-morbidities such as Parkinson disease or diabetes. These patients benefit from an intraoperative gastrostomy to decompress the stomach or a feeding jejunostomy to avoid the risk of TPN.

Duodenal dissection can be difficult in patients with chronic scarring; in these patients we recommend a truncal vagotomy plus a Hofmeister type gastrojejunostomy. The risk of fistula rate from the duodenal stump is also increased in these patients, so duodenal decompression through a lateral duodenostomy in the second portion of the duodenum decreases the risk in elderly patients.

Gastric Polyps

Gastric polyps are nodules of tissue, either sessile or pedunculated, that protrude into the gastric lumen [39]. Gastric polyps are seen in 0.5–2% of all endoscopies; most of them are asymptomatic but occasionally gastric polyps can grow, erode, and bleed. Large polyps can produce GOO [40–42]. Several types of gastric polyps can be found but the three most common in elderly patients are hyperplastic polyps, fundic gland polyps, and adenomatous polyps. Uncommon type of polyps include inflammatory fibroid polyps, xanthomas, Peutz-Jegher type hamartomatous polyps, juvenile polyps, gastric polyps associated with Cowden disease, and finally gastric polyps associated with Cronkhite–Canada Syndrome [43].

Hyperplastic Polyps

Hyperplastic polyps are the most common variety found during endoscopies [41–43]. The incidence increases with age (mean age of diagnosis is 64–75 years) and they are more prevalent in women. Hyperplastic polyps are usually asymptomatic but are associated with other gastric diseases such as *H. pylori* infection, autoimmune gastritis, ZE syndrome, antral vascular ectasia, gastric amyloidosis, or cytomegalovirus gastritis [43]. Gastrin plasma levels are higher than controls [39]. The most common location is the antrum followed by the fundus and body. The mean size is 1 cm, although larger hyperplastic polyps have been reported. The diagnosis is usually incidental and, while an upper endoscopy is being done for another reason. These polyps are usually sessile. The typical histological findings show elongated, dilated, tortuous foveolae lined by mucin-containing epithelium and edema of the lamina propria [42]. The natural history is variable. *H. pylori* eradication is associated with regression [40]. Most hyperplastic polyps are benign and asymptomatic, though a routine biopsy is recommended because the final histology reports dysplasia or carcinoma in 1.5–4% of the patients. This risk of malignancy is higher in polyps larger than 2 cm [42, 43].

Fundic Gland Polyps

These polyps are the second most common type of benign gastric polyps. They can be found sporadically or associated with familial adenomatous polyposis at any age. The most common location is in the fundus. Gastrin values are usually normal and are not strongly associated to *H. pylori* infection [39, 41]. Histology reveals cystic dilated glands lined by parietal and chief cells [42]. These polyps can regress spontaneously; routine follow-up is not required because they are not premalignant [39].

Adenomatous Polyps

The incidence of these polyps increases with age. They are associated with atrophic gastritis and are more prevalent in countries with high incidence of gastric cancer [42]. The median age of diagnosis is 67 years [40]. The most common location is the antrum, and gastrin levels do not differ from controls. The risk of malignancy is higher in adenomatous polyps than any other gastric polyp, especially if the size is greater than 2 cm (40–50% risk of malignancy) [41]. *H. pylori* eradication does not cause regression. Routine excision is recommended because they may be malignant [40].

Dieulafoy Lesion/Malformation

Dieulafoy lesion is an abnormal submucosal artery associated with a minute mucosal defect frequently associated with bleeding. It causes between 1 and 5.8% of acute nonvariceal upper GI bleeding. The most common location is the stomach followed by the first portion of the duodenum but they can occur throughout GI tract or in the bronchial tree. The most common location in the stomach is the fundus and body [44]. The histology reveals a submucosal artery that does not undergo the usual ramification within the wall of the stomach or failure to diminish to the minute size of the mucosal capillary vasculature without any inflammation or defect in the mucosa [45]. It is more common in men. The mean age of diagnosis is 63 years, so they are frequently associated with co-morbidities. Most patients develop melena and hematemesis associated with hemodynamic stability. The treatment follows the same principles described previously for bleeding peptic ulcers; the initial goal is hemodynamic stabilization followed by an upper endoscopy. The same endoscopic techniques described for PUD are used to stop bleeding. The success rate is >90% [46]. In patients who do not respond to endoscopic therapy, local wedge resection of the lesion is indicated.

Gastroparesis

Gastroparesis indicates impaired transit of intraluminal content from the stomach to the duodenum without a mechanical obstruction [47]. It affects 4% of the population.

Etiology

The most common causes of gastroparesis are diabetes, idiopathic, and surgery; however, the most common etiologies in the elderly patient are as follows:

1. *Diabetes.* Gastroparesis is present in 30% of the patients with type 2 diabetes [48]. Different theories explain this effect. Since gastroparesis is seen in patients with other manifestations of autonomic neuropathy, it is believed that autonomic neuropathy contributes to the development of gastroparesis. Diabetes decreases the number of interstitial Cajal cells, induces smooth muscle fibrosis and decreases the neurons present in Auerbach's plexus. Hyperglycemia decreases gastric emptying [48]. Diabetes is the most common cause of gastroparesis in elderly patients because diabetes is one of the most common co-morbidities seen in this population.
2. *Upper GI surgery.* Any surgery that involves the distal esophagus, stomach, or duodenum can be complicated by

delayed gastric emptying. Unfortunately upper GI malignancies that require surgery are more common in older patients. This complication is also seen in benign diseases; gastroparesis may occur after any surgery for PUD or anti-reflux procedures.

3. *Neurological diseases.* Parkinson disease and cerebrovascular accidents are associated with gastroparesis. Parkinson disease is present in 7% of patients with gastroparesis [48].
4. *Drugs.* Elderly patients often require drugs that delay gastric emptying such as calcium channel antagonists, L-dopa, opiates, tricyclic antidepressants, and aluminum antacids [47].
5. *Other co-morbidities.* Renal insufficiency, hypothyroidism, previous abdominal irradiation, cirrhosis, chronic pancreatitis, and paraneoplastic syndromes can produce gastroparesis.

Clinical Manifestation

The most common symptoms are nausea, vomiting, bloating, early satiety, epigastric pain, and belching. Although in severe gastroparesis the previous symptoms present with liquid meals, they are more frequent with solid meals. The physical examination usually shows abdominal distention, mild pain, and tympanic percussion in epigastrium, but in severe cases dehydration is evidenced by tachycardia, orthostatic hypotension, poor skin turgor, and dry mucous membranes. Succussion splash is also present in severe cases.

Gastroparesis should be suspected in any patient with predisposing conditions associated with the symptoms previously described. An extensive workup can rule out cancer, dyspepsia, GOO secondary to PUD, pancreatitis, GERD, cyclic vomiting syndrome, chronic pancreatitis, superior mesenteric, and rumination syndrome. An upper GI radiographic study with contrast plus an upper endoscopy are frequently required to rule out any anatomical obstruction. Retained food in the stomach (with proper fasting) without anatomical obstruction increases the probability of gastroparesis. The gold standard for diagnosis is gastric emptying scintigraphy. In this test the patient receives a solid meal (typically scrambled eggs) mixed with ⁹⁹Technitium sulfur colloid. Gastric emptying is measured after 2, 3, and 4 h. The diagnosis is confirmed if more than 60 or 10% of the meal is retained after 2 and 4 h, respectively [49]. Other useful diagnostic tools are ¹³C-labeled octanoate breath test, abdominal ultrasound evaluating gastric emptying of liquid meals, magnetic resonance imaging, single-photon emission CT, radiopaque markers, swallowed capsule telemetry, antroduodenal manometry, and electrogastrigraphy. These techniques are available in specialized centers [50].

Treatment

The initial goal of therapy is to correct any preexisting dehydration or electrolyte disorders. The medical treatment has different components: dietary recommendations, control of predisposing conditions, and drug therapy.

In elderly patients, predisposing conditions are irreversible or difficult to treat. However, good metabolic control and replacement of any drug that delays gastric emptying is required. Meals rich in fiber or fat should be avoided because they delay gastric emptying; carbonated beverages should also be avoided. Frequent small meals are better tolerated than larger meals [48]. Prokinetic drugs improve gastric emptying. In the USA only two prokinetic agents, erythromycin and metoclopramide, are FDA approved for gastroparesis. Different studies have shown that erythromycin is the most potent agent because it activates motilin receptors and increases both antral peristalsis and gastric emptying. Metoclopramide is a benzamide that increases the contraction in the esophagus, fundus, and antrum; it also elevates the lower esophageal sphincter pressure and improves antral–pylorus–duodenal coordination. It is also helpful to control vomit [51]. Nausea and vomit are present in 92 and 84% of the patients, respectively, therefore antiemetics are also indicated. The most useful agents are phenothiazines (prochlorperazine and tiethyperazine). Serotonin 5-HT₃ receptor antagonists may be helpful because they do not affect gastric emptying. Muscarinic M1 receptors antagonists and H₂RA are not recommended because they inhibit gastric emptying [48]. Tricyclic antidepressants have anticholinergic activity, therefore they decrease gastric emptying; however, low doses can improve nausea and vomit. There are no prospective studies evaluating this effect [50].

The role of surgery in gastroparesis is limited to patients with severe gastroparesis that require multiple hospitalizations plus enteral or parenteral nutrition and those patients who fail medical treatment. Surgery relies on the placement of gastric stimulation devices that alter the gastric myoelectric neural network and interrupt gastric arrhythmias [52]. Through laparoscopy or open approach, two electrodes are placed 1 cm apart in the muscularis propria along the greater curvature 10 cm proximal to the pylorus. The electrodes are connected to a neurostimulator located in a subcutaneous pocket in the left flank [52]. This device has only been implanted in patients with severe gastroparesis. A recent study showed that gastric electrical stimulation produces a good outcome in 70% of the patients, most of whom are able to tolerate oral diets after surgery and have a significant increase in the body mass index [52].

For patients with refractory symptoms placement of a palliative gastrostomy or feeding jejunostomy should be considered.

Complications After Gastric Surgery

It is not uncommon for elderly patients to develop complications after gastric surgery. Each region has a particular response to food ingestion, which are mediated by the vagus nerve. The proximal stomach (fundus) is the main reservoir for liquids; and shortly after liquid ingestion there is a decrease in the tone in the fundus which allows liquid storage. Antral motility is increased by the ingestion of solid meals, it triturates large particles; only 1–2 mm particle pass through the duodenum. The pylorus controls the transit of food particles to the duodenum and limits alkaline reflux. Any surgery that involves the intra-abdominal esophagus, stomach, and duodenum can affect the motor functions of the stomach. The most common postgastrectomy syndromes are as follows:

Dumping Syndrome

It can present after any vagotomy, drainage procedure, or gastric resection. Between 25 and 50% of the patients have some manifestations related to dumping syndrome. In approximately 5–10% of the patients these symptoms are significant and in 1–5% of the patients produce disability. After vagal denervation, the stomach loses the relaxation and accommodation reflexes; therefore, it cannot function as a reservoir. In case a drainage procedure is added, gastric emptying cannot be controlled because the size of the particles is no longer regulated. In healthy persons, the presence of food in the duodenum exerts a negative feedback in gastric emptying, this loop is lost after drainage procedures such as a Billroth II. Dumping syndrome can be divided into early and late dumping syndrome.

Early dumping syndrome presents 10–30 min after food ingestion, the rapid emptying of hyperosmolar meals into the duodenum or jejunum induces water diffusion from the intravascular space to the intraluminal space and the release of serotonin, pancreatic polypeptide, enteroglucagon, peptide YY, glucagon like peptide, vasoactive inhibitory peptide, neurotensin, and epinephrine. These substances induce diaphoresis, weakness, dizziness, flushing, palpitations, fullness, crampy abdominal pain, nausea, vomit, and diarrhea.

Late dumping is seen after 2–4 h after the ingestion of food. The rapid increase of carbohydrate concentration in the intestinal lumen induces a rapid absorption of carbohydrates with hyperinsulinism which creates reactive hypoglycemia. The clinical difference is that patients present only with vasomotor symptoms and no GI symptoms [53].

The diagnosis is suspected in patients with a previous gastric surgery, it can be confirmed with a glucose oral challenge test, with a hydrogen breath test after glucose ingestion or with gastric emptying scintigraphy. Late dumping

syndrome is diagnosed measuring the concentration of glucose 60–180 min after the ingestion of food [54].

The mainstay of treatment are diet modifications, liquids should be ingested 30 min after the ingestion of solids, simple carbohydrates should be avoided, supplemental fiber is recommended, because it decreases gastric emptying. In case symptoms are persistent, octreotide or acarbose can help to control the symptoms. At least 1 year of medical treatment is recommended before surgery is considered. The best surgical therapy is to convert the previous procedure to a Roux en Y gastrojejunostomy, because this procedure decreases gastric emptying [54].

Postvagotomy Diarrhea

It is seen after vagotomy. The physiopathology is unclear, some theories that can explain this complication are denervation of the small intestine, gallbladder, and common bile duct; another theory is rapid gastric emptying associated with rapid intestinal transit that leads to malabsorption. The diagnosis should be suspected in every patient with the antecedent of gastrectomy and a negative workup that rules out other causes of diarrhea. The initial treatment is dietary modification (avoid lactose, decrease liquid ingestion before meals), use of anti-diarrheal agents (loperamide). For refractory untreatable diarrhea the anti-peristaltic interposition of a jejunal limb after 100 cm of the gastrojejunostomy is a possible treatment [55].

Gastroparesis or Delayed Gastric Emptying

Gastric surgery is responsible approximately of 10% of all gastroparesis cases [47]. This complication was described previously.

Afferent Loop Syndrome

It is the result of an obstructed afferent limb secondary to stomal edema, anastomosis, kinking, scarring, stricture, adhesions, internal hernias, or cancer. It can occur acutely 1 or 2 weeks after surgery or chronically. It occurs in 0.3% of the patients that had a Billroth II. The manifestations are abdominal pain most of the time in the right upper quadrant, nausea, nonbilious vomit; however, if the limb is partially obstructed the abdominal pain is relieved after vomit. In severe cases the chronic obstruction can result in jaundice or pancreatitis. The diagnosis is confirmed with an endoscopy that demonstrates the obstruction. The initial treatment can

be endoscopic using balloon dilation, but if it persists the gastrojejunostomy should be converted to a Roux en Y gastrojejunostomy. A second option is a Braun entero-enterostomy between the afferent and the efferent limb [56].

Efferent Syndrome

It results when the efferent limb of a gastrojejunostomy is obstructed. It can also be acute or chronic and it is manifested as abdominal pain, epigastric distention, and bilious vomit. The diagnosis can be done with an upper GI endoscopy or an upper GI transit study that show the obstruction. Possible etiologies are limb kinking, retroanastomotic herniation of the efferent limb or adhesions. The treatment is surgical, either converting a Billroth II procedure into a Roux en Y gastrojejunostomy or revising the initial anastomosis [55].

Duodenal Stump Leak

It presents in patients that have undergone an antrectomy. It is the dehiscence of the initial duodenal closure, and it is common when there is previous inflammation and scarring in this area but can also be a consequence of an incomplete duodenal mobilization or distal obstruction. It can be avoided with a Kocher maneuver to ensure that the closure is tension free; however, if the area has important fibrosis or acute inflammation, a lateral duodenostomy in the second portion of the duodenum help to create a controlled duodenal fistula.

Alkaline Gastritis

After a Billroth II, Billroth I, or pyloroplasty, 5–15% of the patients develop gastritis associated with bilious reflux. Patients complain of epigastric pain, nausea, and bilious vomit. The diagnosis is done with an endoscopy that shows gastric inflammation in the presence of bile. For patients with severe symptoms the previous anastomosis can be converted to a Roux en Y gastrojejunostomy.

Summary

- The major risks factors to develop PUD in elderly patients are *H. pylori* infection and NSAIDs ingestion.
- 50–60% of elderly patients will have an acute complication (bleeding or perforation) as the first clinical manifestation of PUD.

- *H. pylori* eradication decreases the risk of recurrence of PUD complications.
- The outcome associated with PUD complications in elderly patients is worse than young patients.
- Hyperplastic polyps are the most common type of polyps found in the stomach of elderly patients.
- Adenomatous gastric polyps have increased risk of malignancy.
- Diabetes is the most common etiology of gastroparesis in elderly patients.

Chapter 62

Gastric Cancer in the Elderly

Daniel Albo, Daniel A. Anaya, and David H. Berger

In recent decades, improved socioeconomic conditions, medical progress, and preventive medicine have lengthened life expectancy in our society and consequently increased the elderly population. Despite an overall drop in the incidence of gastric cancer in the Western world, increased life expectancy has resulted in a growing proportion of elderly patients with gastric cancer. Today, more than 30% of patients with gastric cancer are older than 70 years. Although some characteristics of this disease are similar in younger and older patients, management of gastric cancer in the elderly exhibits some significant differences and presents unique challenges compared to management in younger patients. In this chapter, we will explore some of the unique epidemiological and pathological features of this disease in the elderly. Furthermore, we will try to elucidate the ideal surgical treatment strategies and the role of multimodality management in this challenging group of patients.

Gastric Cancer in the Elderly: Epidemiological and Pathological Considerations

Worldwide, gastric cancer is the second most common cause of cancer-related death with over 700,000 deaths annually. In the USA, over 21,500 new cases of gastric cancer were estimated to occur in 2008 [2]. Advancing age is a risk factor for the development of gastric cancer. The incidence of gastric cancer increases linearly with advancing age. In the USA the age-adjusted risk of developing gastric cancer for an individual between the ages of 40 and 49 is 3.6 per 100,000. The incidence increases to 20.9 per 100,000 for

people between the ages of 60 and 69 and to over 50 cases per 100,000 population above the age of 80 (Fig. 62.1). Similarly, the mortality rate for gastric cancer increases with age and is similar to the incidence rate (Fig. 62.2) [1]. This is likely due to the fact that most patients with gastric cancer in the USA present at an advanced stage. The majority of patients with gastric adenocarcinoma will present with either regional (30%) or distant (35%) disease [2].

The overall incidence of gastric cancer has been decreasing over the past 30 years. This decrease in the incident rate is age related. There has been a greater than 40% decline in the incidence of gastric cancer in Americans aged 65 and older compared to only a 7% decrease in the incidence of gastric cancer in patients younger than 65 (Fig. 62.3) [3]. The age-related decline in gastric cancer incidence may be due to an increase in the incidence of proximal gastric cancer compared to distal gastric cancer [4]. Proximal gastric cancer appears to occur more frequently in younger individuals. The mean age of patients diagnosed with proximal gastric cancer is 67.7 years compared to a mean age of 71.5 years for patients with distal gastric cancer. Additionally, more than 60% of patients with distal gastric cancer are aged 70 years or while only 49.5% of patients with proximal gastric cancer are in this age group [5].

The characteristic pathological features of gastric carcinoma in elderly people are somewhat different than in younger patients [6, 7]. Gastric cancer in the elderly tends to involve the lower third of the stomach and shows a higher incidence of histopathologically well-differentiated adenocarcinoma. Multiple and metastatic cancers are more common in aged people. In a comprehensive analysis of 994 surgical patients aged 65 years or older, Arai et al. studied the pathologic characteristics of gastric cancer in the elderly [8]. Pathological findings in the very old group (older than 85 years; $n=126$) were compared with those in younger groups (65–74 years [young-old group]; $n=356$) and (75–84 years [middle-old group]; $n=512$). While the male-to-female ratio significantly decreased with advancing age, the relative odds of gastric cancer in men was higher than that in women across all age groups. In the very old

FIGURE 62.2 Age-adjusted mortality from stomach cancer per 100,000 population, United States Cancer Statistics 2001–2005 [1].

group, cancer of the lower third of the stomach tended to increase with advancing age, and accounted for 43.7% of cases. In the overall population, differentiated-type adenocarcinoma accounted for 89.6% in the early cancers and 50.3% in the advanced cancers. The proportion of cases involving differentiated-type carcinoma significantly increased with advancing age in early cancer and female advanced cancer cases, whereas no significant change was found in male advanced-cancer patients. In the very old group, lymph node metastasis was found in 5.4% of early cancers and 72.7% in advanced cancers. The incidence of multiple cancers significantly increased with advancing age ($P < 0.05$; 10.7% in the younger-old group, 12.7% in the middle-old group, and 19.0% in the very old group).

Chronic infection with *Helicobacter pylori* is a risk factor for distal but not proximal gastric cancer. Proximal gastric cancer has been associated with alcohol use, gastroesophageal reflux disease, and obesity [9]. Epidemiological

Cancer sites include invasive cases only unless otherwise noted. Incidence source: SEER 9 areas (San Francisco, Connecticut, Detroit, Hawaii, Iowa, New Mexico, Seattle, Utah, and Atlanta). Rates are per 100,000 and are age-adjusted to the 2000 US Std Population (19 age groups – Census P25-1130). Regression lines are calculated using the Joinpoint Regression Program Version 3.3, April 2008, National Cancer Institute.

FIGURE 62.3 Gastric cancer age-adjusted SEER incidence rates by age at diagnosis/death. Stomach, all races, male, 1975–2005 (SEER 9). Cancer sites include invasive causes only unless otherwise noted. Incidence source SEER 9 areas (San Francisco, Connecticut, Detroit, Hawaii, New Mexico, Seattle, Utah, and Atlanta). Rates are per 100,000 and age-adjusted to the 2000 US Std population (19 age groups – Census P25-1130). Regression lines are calculated using the Joinpoint Regression Line Program Version 3.3, April 2008, National cancer Institute.

and clinical studies indicate that *H. pylori* infection is associated with a greater risk of distal gastric cancer. The International Agency for Research on Cancer and The World Health Organization have characterized *H. pylori* as a group I carcinogen. It has been postulated that *H. pylori* infection contributes to gastric cancer, through a sequence of events: infection → acute gastritis → chronic superficial gastritis → atrophic gastritis → atrophy → intestinal metaplasia → dysplasia → adenocarcinoma [10]. The seroprevalance of *H. pylori* increases with age. Whereas only 16.7% of individuals aged 20–29 have clinical evidence of *H. pylori* infection, greater than 56% of individuals above age 70 are infected. The association of *H. pylori* infection with age likely explains the increased incidence of distal gastric cancer seen in the elderly population. Furthermore, the

declining incidence of gastric cancer in the elderly is likely a result of the declining prevalence of *H. pylori* infection in the USA.

Surgical Therapy for Gastric Cancer in the Elderly (Table 62.1)

Age Alone is not a Contraindication for Gastrectomy

A German study from Gretschel et al. investigated the value of individual risk-adapted therapy in geriatric patients [11]. They performed a consecutive analysis of 363 patients undergoing potentially curative surgery for gastric cancer. All patients underwent extensive preoperative workup to assess surgical risk. Comorbidities, tumor characteristics, type of resection, postoperative morbidity and mortality, recurrence rate, overall survival, and disease-free survival were evaluated in three age groups: <60 years, 60–75 years,

and >75 years. Not surprisingly, investigators found that there was an increased rate of comorbidities in the higher age groups (51% vs. 76% vs. 83%; $P < 0.05$). Cardiovascular and pulmonary diseases were the most common comorbid conditions. With advancing age there was a decrease in the rate of both total gastrectomy (74, 54, 46%; $P < 0.05$) and D2 lymphadenectomy (78, 53, 31%; $P < 0.05$). The 30-day mortality in the three age groups was 0, 1, and 8%, respectively ($P < 0.05$). There was only a slight difference in tumor recurrence rate (35, 37, and 27%; $P = 0.437$), with no significant difference in 5-year cancer-related survival (61, 53, 61%; $P = 0.199$). The authors concluded that patient selection and risk-adapted surgery in elderly patients results in acceptable therapeutic results comparable to younger patients. Additionally, these authors stated that limited surgery in elderly gastric cancer patients with high comorbidities does not necessarily compromise oncological outcome.

Looking to define the risk factors that predict 30-day morbidity and mortality after gastrectomy for cancer in Veterans Affairs (VA) Medical Centers, Grossman et al. reported data gathered prospectively by the VA National Surgical Quality Improvement Program on 708 patients

TABLE 62.1 Tailored surgical therapy for the elderly with gastric cancer

Study origin	<i>N</i>	Perioperative morbidity (elderly vs. young)	Perioperative mortality (elderly vs. young)	DFS (elderly vs. young)	OS (elderly vs. young)	Notes	References
Germany	363	Higher	Higher	Minimal decrease	Same	Limited surgery does not compromise oncological outcomes in the elderly with comorbidities	[10]
USA	708	Higher	Same	–	–	VA study evaluated risks factors for perioperative morbidity and mortality	[11]
China	2,613	–	–	Same	Higher	Limitations: age cutoff at 60; no analysis of comorbidities	[12]
Japan	289	Higher	Higher	–	Lower	Lower rate of curative surgery observed in the elderly	[13]
China	433	Higher	Higher	Same	Same	Limited resection recommended in the very old	[14]
Korea	719	Higher	Same				[15]
Japan	93	All patients >80 years old	–	D2>D1	D2>D1	D1 vs. D2 Resections compared. Recommended D2 in patients with good functional status	[16]
Italy	110	All patients >80 years old	–			Higher comorbidities resulted in higher mortality; radical resection recommended only for fit patients	[17]
United Kingdom	180	Higher	Same	–	–	By tailoring the extent of resection and balancing risk and radicality, gastric cancer surgery can be performed with low mortality in the elderly	[19]

VA veterans administration, DFS disease free survival, OS overall survival

undergoing gastrectomy for cancer in 123 participating VA medical centers from 1991 to 1998 [12]. Independent variables analyzed by the authors included 68 preoperative patient characteristics and 12 intraoperative variables; the dependent variables were 21 defined adverse outcomes and death. Predictive models for 30-day morbidity and mortality were constructed by using stepwise logistic regression analysis. Overall, the 30-day morbidity rate was 33.3% (236 of 708). The overall 30-day mortality rate was 7.6% (54 of 708). Significant positive predictors of morbidity ($P < 0.05$) included current pneumonia, American Society of Anesthesiologists class IV (threat to life), partially dependent functional status, dyspnea on minimal exertion, preoperative transfusion, extended operative time, and increasing age. Significant positive predictors of mortality ($P < 0.05$) included do not resuscitate status, prior stroke, intraoperative transfusion, preoperative weight loss, preoperative transfusion, and elevated preoperative alkaline phosphatase level. Although they found an increase in overall morbidity, age alone was not an independent risk factor for increased perioperative mortality after gastrectomy in elderly patients.

In one of the largest series published on outcomes after resection for gastric cancer, Chinese investigators analyzed the factors influencing the prognosis of patients with gastric cancer after surgical treatment [13]. In this retrospective study, 2,613 consecutive patients with gastric cancer were studied. Of these patients, 2,301 received operations, and of these, 1,975 underwent surgical resection of the tumors (891 received palliative resection and 1,084 received curative resection). Of the patients with surgical resection of the tumors, the overall 1-, 3-, and 5-year survival rates were 82.7, 46.3 and 31.1%, respectively, with the 5-year survival rate being 51.2% in patients with curative resection, and 7.8% for those with palliative resection. The 5-year survival rate was 32.5% for patients with total gastrectomy, and 28.3% for those with total gastrectomy plus resection of the adjacent organs. The factors that independently correlated with poor survival in this study included advanced stage, upper third location, palliative resection, poor differentiation, Bormann classification type IV, tumor metastasis (N3), tumor invasion into the serosa and/or contiguous structures, proximal subtotal gastrectomy for upper third carcinoma, and D1 lymphadenectomy after curative treatment. Age alone was not found to be an adverse independent prognostic factor of outcome. Moreover, 5-year survival was higher in patients over the age of 60 compared to younger patients (36.2% vs. 29.2%, respectively; $P = 0.05$). The limitations of this study include a relative young age of cutoff to define the elderly population (60 years and older), the lack of analysis on comorbidities in the different age groups, and the lack of information on tumor characteristics specific to the different age groups. Nonetheless, the authors concluded that primary gastric cancer should be resected with a radical operation as

long as the local conditions permitted in order to prolong patient survival and improve their quality of life regardless of age at the time of presentation.

A study from Japan analyzed outcomes after gastrectomy for gastric cancer on 50 patients ≥ 80 years of age compared to 239 patients ≤ 60 years of age [14]. The incidence of advanced gastric cancer in the older vs. younger groups was 59.6% vs. 27.9%, respectively ($P < 0.01$). The tumor size was significantly larger in the older group. The tumor location in the older group predominantly involved the upper third of the stomach, while in the younger group, the middle third of the stomach was primarily involved. Histologically, the incidence of differentiated tumor types was 65.1% vs. 50.5% ($P < 0.05$), and undifferentiated types, 34.9% vs. 49.5% ($P < 0.05$), in the older and younger groups, respectively. Retrospective comparisons conducted between the older and younger groups revealed the following curative resectability rates: 52.0% vs. 74.5% ($P < 0.01$); hospital mortality rate: 2% vs. 0%; overall 5-year survival rate: 46.1% vs. 71.1% ($P < 0.01$); and a 5-year survival rate in patients who underwent curative resection of 65.0% vs. 88.8% in the older vs. younger age groups, respectively. These results suggest that the survival of elderly patients with gastric cancer is worse than that of younger patients because of a lower curative resection rate of advanced cancers. However, the survival rate in elderly patients is similar to that in younger patients if a curative resection is performed.

The Case for Tailoring the Extent of Resection According to Patient Factors

Contrary to the above reports, a study from China found an increase in operative mortality after gastrectomy in the elderly [15]. In this study, 433 patients aged > 65 years who underwent gastric resection for gastric adenocarcinoma were analyzed. Two groups were considered: patients aged 65–74 years and those > 74 years. Most of the patients (78.1%) had advanced disease, and nearly half (41.3%) had associated chronic conditions. Resections with curative intention were performed in 83.6% of patients. The overall operative morbidity and mortality rates were 21.7 and 5.1%, respectively. Although operative procedures were similar in both groups, patients aged > 74 years had a higher mortality rate than those aged 65–74 years (10.1% vs. 3.5%; $P = 0.034$). Age and extent of gastric resection were two independent factors negatively affecting mortality. The cumulative survival rates for patients who underwent curative resection were 86.2, 72.4, 67.2, 62.9, and 60.0% at 1, 2, 3, 4, and 5 years, respectively. Nearly all patients (96%) after surgery had normal work and daily activities. Some patients appeared to lack energy (16%) or experienced a period of anxiety or depression. There was

no statistical difference in survival and quality of life assessed by the Spitzer index after curative resection between the two groups. The authors concluded that resection with curative intention can be performed for the elderly with acceptable morbidity and mortality rates, possible long-term survival, and good quality of life, but a limited operation should be considered in the very elderly patients.

Another study from Korea on 719 consecutive patients who underwent operations for gastric cancer also found an increased risk of perioperative morbidity, but no increase in mortality after surgical resection for gastric cancer in elderly patients [16]. Overall morbidity and mortality rates were 17.4 and 0.6%, respectively, and the rates of surgical and nonsurgical complications were 14.7 and 3.3%. Morbidity rates were higher in patients aged over 50 years (odds ratio 1.04, 95% confidence interval 1.02–1.06), when the gastric tumor was resected with another organ (36% for combined resection vs. 15.4% for gastrectomy only; odds ratio 3.25, 95% confidence interval 1.76–6.03) and when gastrojejunostomy was used for reconstruction after subtotal gastrectomy (17.0% for Billroth II vs. 9.5% for Billroth I; odds ratio 2.00 (95% confidence interval 1.05–3.79)). The authors concluded that age, combined resection, and Billroth II reconstruction after radical subtotal gastrectomy were independently associated with the development of complications after gastric cancer surgery.

A study on 93 patients who underwent gastrectomy for gastric cancer evaluated the benefit of R2 vs. R1 gastrectomy for gastric cancer in Japanese patients over 80 years of age [17]. The clinical and pathological characteristics of the patients in the two groups were comparable at the time of surgery, except that the group who underwent R1 gastrectomy was older. R2 gastrectomy involved a significantly longer operation time ($P < 0.01$) and greater intraoperative blood loss ($P < 0.05$) when compared to R1 gastrectomy, but no patient undergoing this extensive surgery died. The difference in the morbidity rate between the two groups was not statistically significant. The 5-year survival rate was 55.8% in the R1 group and 65.4% in the R2 group. When gastric cancer invaded the serosa and/or secondary nodes, a substantial increase in survival time was gained with R2 gastrectomy when compared to an R1 operation. These findings suggested that an R2 gastrectomy is feasible, even for patients over 80 years, but seems to be indicated mainly when the carcinoma had invaded the serosa and/or secondary nodes and the patients are at good risk for major surgery.

A group of Italian surgeons recently reported on their 18-year experience with 110 patients aged 80 years and over affected with gastric cancer [18]. Postoperative morbidity and mortality rates and risk factors affecting their incidence were examined by univariate and multivariate analysis. Operability and resectability rates were 70.9 and 47.3%, respectively. Of the resective procedures, 78.8% were subtotal gastrectomies. In 9.6% of cases, combined resections

were performed. Twenty-five patients (32.1%) experienced postoperative complications; overall mortality rate was 12.8%. In resective procedures, morbidity and mortality were 26.9 and 3.8%, respectively. Statistical analysis identified the number of preexisting medical illnesses as an independent predictor of morbidity and mortality. The crude 5-year survival rate of curatively resected cases was 43%. Although multiple medical illnesses led to higher operative mortality, neither the presence of postoperative complications nor the number of preexisting medical illnesses significantly influenced the 5-year survival rate of curatively resected patients. The authors concluded that with careful patient selection, gastric surgery provides good immediate and long-term results even in very old patients. However, the authors also concluded that subtotal gastrectomy with limited lymphadenectomy should be the preferred procedure; total gastrectomy, combined resections and extended lymphadenectomy should be performed only when necessary, in patients with fewer than two illnesses. Surgery should be avoided in elderly patients with highly advanced disease, if multiple medical illnesses are present.

Another Japanese study evaluated the relationship between operative procedures for treatment of patients with gastric carcinoma and complications with special reference to the age of patients [19]. In this study, the patients were divided into four age groups: 50–59; 60–69; 70–79; and over 80 years. In elderly patients, proximal gastrectomies were not performed, resection of the neighboring organs was seldom performed and lymph node dissection was usually limited to the primary and secondary nodes. There was no significant difference in the rate of postoperative complications between groups. Although only limited surgery was performed for patients of 80 years and over, there was no significant difference in age-corrected cumulative survival rate between groups. This study concluded that limited resection may allow safe surgical treatment for patients of 80 years and over with gastric carcinoma, without a negative effect on prognosis.

In a study from the UK of 180 consecutive patients undergoing resection for gastric adenocarcinoma with curative intent the balance between risk and radicality of resection was evaluated [20]. The extent of lymphadenectomy was based upon preoperative and intraoperative staging and balanced against the patient's age and fitness. In this study, 83 patients underwent subtotal or distal partial gastrectomy and 97 patients underwent total or proximal partial gastrectomy. Operative procedures were as follows: D1 lymphadenectomy ($n = 62$); modified (spleen and pancreas preserving) D2 lymphadenectomy ($n = 73$); D2 lymphadenectomy ($n = 42$); and extended resection ($n = 3$). The TNM classification for these patients was: stage 1 ($n = 45$); stage 2 ($n = 37$); stage 3 ($n = 61$); and stage 4 ($n = 37$). Of the patients, 48 developed postoperative complications including 17 patients with a major surgical complication. The in-hospital mortality was

1.7%. Predicted mortality was 21.4 and 7.8%, respectively. Disease-specific 5-year survival according to stage was 85.4, 64.2, 33.3, and 6.9%. The authors concluded that by tailoring the extent of resection and balancing risk and radicality, gastric cancer surgery can be performed with low mortality in Western patients.

Adjuvant and Neoadjuvant Therapies in Gastric Cancer

Despite improvements in diagnosis and surgical management of patients with gastric cancer, cure rates are still extremely low and long-term survival has remained stagnant over the last few decades [21]. Studies using worldwide [22] and national US cancer registries [2] have revealed current 5-year overall survival (OS) rates of 20–24%, a modest increase as compared to 17% seen in the early 1970s [2]. Similarly, outside Asian countries, and with no formal standardized screening programs, most patients with gastric cancer are diagnosed with advanced stages with less than a quarter (24%) presenting with early gastric cancer at time of diagnosis [2]. Additionally, even in the setting of curative resection, at least 50% of patients develop early (within 2 years) recurrence, generally evenly distributed between distant and locoregional sites [23]. Considering these outcomes, it is not surprising that additional therapies have been and continue to be evaluated as a means to achieve better long-term outcomes. During the last decade two pivotal studies [24, 25] helped define a milestone in the approach to patients with gastric cancer and have contributed to shifting the standard of care from surgery alone to multimodality therapy.

History and Current Standards in the General Population

More than 30 randomized clinical trials have been performed evaluating the role of different chemotherapy agents in the adjuvant setting with inconclusive results regarding its benefit and impact on OS. Most are old studies evaluating outdated regimens including single or combination therapies of mytomicin C, cytarabine, methyl-lomustine, 5-fluorouracil, doxorubicin, and epirubicin among other agents. Although some of these trials were able to show improved OS, [26–29] others revealed contradictory results [30–32]. In an attempt to clarify this, multiple meta-analysis have been performed [33–36] and although most have shown a benefit of adjuvant chemotherapy, albeit small, the heterogeneity of the studies included in all, as well as the selective benefit

of chemotherapy in some (Asian patients only [36] and nodal-positive disease [34]) precluded any definitive recommendation for the standard use of chemotherapy.

Given the high rate of locoregional recurrence after curative resection, radiation therapy in different settings, has also been explored. A randomized trial by the British Stomach Cancer Group evaluated the role of external beam radiation therapy (EBRT) after resection in patients with stage II and III gastric cancer [37]. Five-year OS was lower for those in the radiation therapy arm as compared to patients having surgery alone or surgery followed by chemotherapy. The effect of intraoperative radiation therapy (IORT) in the treatment of gastric cancer has also been evaluated with studies revealing no effect on OS either [38]. Another strategy has been the use of chemotherapy with radiation therapy in the postoperative setting. A series of studies have been conducted in the past trying to address this strategy for gastric cancer [39–41]. Although two of these trials showed a difference in survival benefiting the treatment arm [40, 41], multiple methodological flaws limited the validity of their results. More recently, a well-designed randomized controlled trial, the Gastrointestinal Cancer Intergroup Trial (INT-0116) [24], assessed the role of postoperative chemoradiation (5-FU/leucovorin and 45Gy of EBRT) in 556 patients with stage IB-IVM0 gastric and gastroesophageal adenocarcinoma after complete (R0) resection. Although the study is criticized due to the high proportion of patients unable to tolerate treatment (~30%) as well as to issues regarding adequacy of radiation technique and surgical resection (>50% of patients had <D-1 lymphadenectomy), results were encouraging revealing a 9% absolute benefit in the 3-year OS of patients in the treatment group as compared to those having surgery alone (3-year OS 50% vs. 41%, respectively, $P=0.005$). This study was the first one showing a clear benefit in OS for patients with gastric cancer and marked the transition from resection alone to multimodality therapy as the standard of care for the management of patients with gastric cancer.

Neoadjuvant approaches have also been evaluated in an attempt to improve survival in patients with resectable gastric cancer as well as an alternative approach for patients presenting with initially unresectable tumors. Proponents of this approach argue that with neoadjuvant therapy, foci of micrometastatic disease can be targeted earlier, tumor response can be assessed, down-sizing can be achieved possibly leading to higher rates of resectability as well as to higher R0 resections and that it allows to select out the patients who will progress while on therapy due to the aggressive behavior of their tumors. An additional benefit is that neoadjuvant therapy tends to be better tolerated, a potentially relevant feature when considering multimodality therapy in elderly or debilitated patients. More recently, investigators from MD Anderson Cancer Center have shown

the prognostic value of response to preoperative chemotherapy as well [43]. The use of preoperative chemotherapy has been well studied in multiple phase I and phase II trials and its feasibility and safety have been well delineated [43–47]. Although a recent phase III study led by the Dutch Gastric Cancer Group evaluating the effect of preoperative chemotherapy in resectable gastric cancer failed to demonstrate any long-term benefit in survival with this strategy [48], a more recent and well-designed study utilizing perioperative chemotherapy has become the gold standard in managing gastric cancer in many places worldwide [26]. The MAGIC trial (Medical Research Council Gastric Infusional Chemotherapy Trial) randomized 503 patients with \geq stage II nonmetastatic gastric and gastroesophageal cancer to surgery alone vs. perioperative chemotherapy [epirubicin/cisplatin/5-FU (ECF) pre- and postoperatively] and surgery. Despite only 42% of patients in the treatment arm completing both pre- and postoperative therapy, intention-to-treat analysis revealed a significant benefit in 5-year OS (36% vs. 23% for the surgery alone group, $P=0.009$). Similarly, patients in the perioperative chemotherapy group were found to have smaller size tumors, more early stage tumors, and had a higher rate of curative resection, arguing in favor of some of the added benefits of response to preoperative chemotherapy. Postoperative complications were similar for both groups. Although this regimen was not tolerated by all patients and only 42% completed therapy, it is hard to argue against the benefit of this strategy and this should currently be considered the standard of care in eligible patients.

More recently, a randomized controlled trial from Japan evaluated the role of adjuvant chemotherapy for 1 year with the oral fluoropyrimidine S-1 as compared to surgery alone in patients with stages II (excluding T1 tumors), IIIA and IIIB gastric cancer undergoing D-2 resections [49]. They randomized a total of 529 patients and found a survival benefit in the treatment arm with 3-year OS of 80.1% vs. 70.1% in the surgery alone group ($P=0.003$) and a relatively low incidence of major toxicities. Although this trial confirms the benefit of multimodality therapy for gastric cancer it is limited by the extent of the operation (100% of patients had D-2 resections), since this type of operation is the exception rather than the rule in western countries, as evidenced by the findings from the INT-0116 trial [25].

Current studies are focusing on the role of preoperative chemoradiation [50, 51], combinations of the MAGIC and INT-0116 trials regimens (CALBG 80101 trial) evaluated in the postoperative setting, and addition of targeted therapies (bevacizumab) to MAGIC-type chemotherapy (MAGIC-B trial) [52]. Additionally, current effective regimens (i.e., ECF) are being evaluated with newer agents such as capecitabine and oxaliplatin, which have shown similar or better

response rates with the added benefit of more favorable toxicity profiles [53]. Future strategies will very likely be characterized by the use of multimodality therapy both in the preoperative and postoperative settings with the emergence of biologic agents as a promising addition to these recent positive findings.

Data on Adjuvant and Neoadjuvant Therapies in the Elderly

When approaching elderly patients with the diagnosis of gastric adenocarcinoma, specific considerations must be included in the decision-making strategy for both the surgical approach and the use of adjuvant/neoadjuvant therapies. At least 60% of patients diagnosed with gastric adenocarcinoma are over the age of 65 and multiple studies have confirmed increasing age as an important predictor of worse long-term outcomes (Fig. 62.2). The specific reason driving this prognostic difference is not clear; however, a series of studies have shown that in the elderly, substandard surgical and systemic therapy is often the rule in patients with colorectal carcinoma [54] as well as in those diagnosed with other gastrointestinal malignancies, including gastric cancer [55, 56]. Specifically, a population level study originated from the analysis of two large cancer registries in France revealed that in patients over the age of 80 years, regardless of the specific gastrointestinal cancer site, chemotherapy was administered in an extremely low number of patients (1.6–5.1%) [55]. These findings have also been confirmed in other larger US registry studies evaluating the use of adjuvant chemotherapy for stage III colorectal cancer, in which increasing age has been identified as independently associated with lower use of this proven effective strategy [57].

In parallel to patient selection in randomized trials from other sites [58], elderly patients are underrepresented in adjuvant and neoadjuvant trials for the management of gastric cancer, complicating the strength of potential inferences made regarding the benefit and/or toxicity of these regimens in this subset of patients. For example, in the INT-0116 trial the median age of patients was 60 and 59 years in the treatment and control arms, respectively, and no additional analysis regarding effectiveness or toxicities was done based on age [25]. The MAGIC trial [26] and the Japanese trial evaluating the role of S-1 [49] had a median age of 62 and 63 years, respectively, and although in the latter there was a set limit of age over 80 for eligibility and in both, patients were well selected to minimize the number of comorbidities (a rare situation in the elderly), both of these trials did have at least 20% of their population over the age of 70 years. Although this proportion does not reflect the typical age distribution of

this disease and despite no specific subset analysis being done to evaluate age as a predictor of response or toxicity, the inclusion of such proportion of elderly patients, albeit small, allows to consider that regimens may be tolerated as well and that their clinical effect on survival may in fact be applicable to older patients too.

To better establish this observation, at least five recent phase II trials have been performed evaluating the tolerability of different regimens for advanced gastric cancer (locally advanced and metastatic) in the elderly and to define the response rates in these patients [58–63]. In 2003, Graziano et al. reported adequate safety with the use of cisplatin/leucovorin/fluorouracil in the elderly population.

More recently [58], with the emergence of the newer platinum class agent oxaliplatin, investigators have evaluated different oxaliplatin-based regimens in the elderly population. The advantage of this newer agent includes better response rates as well as a more favorable toxicity profile with dose-limiting toxicity due to peripheral neuropathy rather than other more complicated and potentially lethal toxicities (i.e., hematologic). These reports have recently shown an overall tumor control rate of approximately 70–80% with overall responses of 32–45%, complete response rates in the range of 2–8%, and grade III toxicities of 7–15% with no reported chemotherapy-induced deaths [59, 61]. The effectiveness of these regimens compares well to those used in the general population and based on these preliminary studies, they appear safe when used for managing elderly patients. The caveats to some of these reports includes the strict selection criteria of patients characterized by good performance status (ECOG 0–1) and the low number of comorbidities, a feature often unrealistic when managing older populations. Additionally, the clinical effectiveness (i.e., impact on survival) of these regimens still needs to be tested specifically for resectable nonmetastatic disease, ideally in the setting of multi-institutional randomized controlled trials with a higher proportion of patients over the age of 65 years.

In summary, multimodality therapy for the management of nonmetastatic gastric cancer has become the standard of care with postoperative chemoradiation and perioperative chemotherapy being the most commonly used approaches. Adjuvant chemotherapy with S-1 for a more prolonged period of time in patients having had a D-2 curative resection is also a proven effective strategy. None of these studies have addressed the effectiveness and/or toxicity profiles of these regimens in the elderly specifically; however, a reasonable proportion of older patients were included and appeared to benefit similarly to younger patients from the two multimodality approaches. Further, perioperative chemotherapy (MAGIC-type regimen), although not tolerated

well by all patients, has the advantage of being started prior to surgery, which can theoretically be better tolerated than after a large operation with all the potential side effects that this could have on older patients as described earlier. Newer regimens with more effective agents and better toxicity profiles have proven to be a safe approach in the elderly specifically. As additional phase III trials evaluating these newer regimens are completed with consistent information regarding their benefit on survival, more solid data will become available to shift the management of older patients from current regimens to those newly tested. Finally, with the improvements in diagnosis, staging, and perioperative care as well as with the worldwide effects of the demographic transition and the so-called increase in the “graying” population, future trials evaluating multimodality approaches in combination with biologic agents need to include a higher proportion of elderly patients that more realistically represent the demographic characteristics of patients with gastric cancer.

Practical Application

Based on these data, we have developed a selective approach to the surgical management of gastric cancer in the elderly. In order to decide the extent of surgical resection (total vs. subtotal gastrectomy) and the extent of lymphadenectomy (D1 vs. D2 lymphadenectomy; Table 62.2 compares the extent of lymphadenectomy in these two techniques) we do not necessarily consider the patient’s chronological age, but his/her biological age. Factors considered in this decision making process include the number and type of comorbidities, functional status, and nutritional status. For the latter, we consider the extent of weight loss and the patient’s albumin level. The following two cases illustrate this selective approach to the surgical management of gastric cancer in the elderly in our practice (Table 62.3).

TABLE 62.2 “D” nomenclature: extent of lymphadenectomy during gastrectomy for gastric cancer

Description	Regions included in resection
D1	Removal of all nodal tissue within 3 cm of the primary tumor
D2	D1 plus clearance of hepatic, splenic, and left gastric lymph nodes
D3 ^a	D2 plus omentectomy, splenectomy, distal pancreatectomy, and clearance of celiac and porta hepatis lymph nodes

^aD3 resections are not currently recommended

CASE STUDY 1

The patient is an 80-year-old male who was status post-antrectomy and truncal vagotomy with a Billroth II reconstruction for peptic ulcer disease over 20 years ago. Over the last 3 months, he developed progressive dysphagia, lost approximately 10 pounds, and reported vague epigastric discomfort. His past medical history included hypertension (well controlled) and gastro esophageal reflux disease. He did not smoke or drink alcohol. He lived independently and was very active. He underwent an esophagogastroduodenoscopy, which revealed a mass in the gastric remnant involving the body and fundus of the stomach. A biopsy of this mass revealed a well-differentiated adenocarcinoma. His serum albumin level was 3.6 mg/dl. A CT scan of the chest, abdomen, and pelvis revealed a thickening of the stomach remnant with

no evidence of regional adenopathy, visceral metastases or carcinomatosis (Fig. 62.4). An endoscopic ultrasound revealed this mass was a eusT3, N0, M0.

Although this patient's chronological age was advanced, he was in excellent functional state, had no severe comorbidities and a good nutritional status. His gastric cancer was potentially curable with multimodality therapy. Therefore, we took an aggressive approach with him, with modern perioperative chemotherapy and radical surgery. He underwent Magic-type perioperative chemotherapy and had a completion gastrectomy with a D2 lymphadenectomy and a Roux-en-Y esophagojejunostomy reconstruction. His final pathology report showed a well-differentiated adenocarcinoma with negative margins and 0/24 lymph nodes positive. The final pathological staging was a T3N0M0. Twenty-six months later he is alive and disease-free and in good functional state.

FIGURE 62.4 CT of the abdomen of an 80-year-old patient with gastric adenocarcinoma. The *arrows* show thickening of the stomach at the level of the fundus and gastro esophageal junction (a) and the body of the stomach (b).

TABLE 62.3 Case presentations: tailoring the radicality of surgery and adjuvant therapy to the patient's functional state

	Case 1	Case 2
Age	80	82
Symptoms	Dysphagia; mild weight loss	Bleeding requiring multiple transfusions; significant weight loss
Comorbidities	HTN, GERD	HTN, COPD, CAD, DM, AAA
	No smoking or alcohol intake	Significant smoking and alcohol consumption
Functional state	Excellent	Poor
Nutritional state	Excellent	Poor
Albumin level	3.6 mg/dl	2.3 mg/dl
Type of gastrectomy	Total gastrectomy	Distal gastrectomy
Extent of lymphadenectomy	D2	D1
Adjuvant therapy	Magic-type, perioperative	Postoperative therapy not tolerated
Surgical pathology report	T3N0M0; 0/24 lymph nodes	T3N1M0; 1/10 lymph nodes
Current status	Disease-free 26 months after surgery; excellent functional state	Disease-free 14 months after surgery; baseline fair functional state

HTN hypertension, GERD gastro esophageal reflux disease, COPD chronic obstructive pulmonary disease, CAD coronary artery disease, DM diabetes mellitus, AAA abdominal aortic aneurysm

CASE STUDY 2

The patient is an 82-year-old male with repeated episodes of upper gastrointestinal bleed requiring several hospitalizations and multiple blood transfusions. He had extensive comorbidities, including severe chronic obstructive pulmonary disease, coronary artery disease, diabetes, hypertension, and an abdominal aortic aneurysm (4.5 cm, stable, nonsymptomatic). He was an active heavy smoker with a history of significant alcohol consumption (quit 5 years prior). He reported a recent weight loss of 15 pounds. He lived in an assisted-living home and his functional state was only fair. His most recent hemoglobin was 8.2 mg/dl after transfusion of two units of blood. His albumin level was 2.3 mg/dl. An esophago-gastroduodenoscopy revealed an ulcer in the antrum of the stomach with raised borders and stigmata of a recent bleed. Biopsies revealed a moderately differentiated adenocarcinoma. A CT scan showed thickening of the antrum and no evidence of visceral metastases or carcinomatosis (Fig. 62.5).

This patient had multiple, severe comorbidities, and a poor functional and nutritional status. The ongoing bleeding was of concern, though, and we decided on a less radical approach with him. We did not consider him a candidate for neoadjuvant therapy. We performed a distal gastrectomy with a limited D1 lymphadenectomy and a Billroth II gastrojejunostomy anastomosis. His final pathology report showed a moderately

differentiated gastric adenocarcinoma with negative margins of resection and 1/10 lymph nodes positive for metastatic disease. The final pathological staging was T3N1M0. Although an attempt to administer postoperative chemoradiation was made by our hematology/oncology colleagues, the patient did not tolerate it well and it had to be stopped. Fourteen months after surgery he has not had any more episodes of gastrointestinal bleed and is back to his baseline functional state. He remains cancer-free.

Conclusion

Gastric cancer remains one of the most common and aggressive malignancies worldwide. Since the incidence of gastric cancer increases linearly with age, and since the average lifespan of the population is increasing steadily, gastric cancer is a significant problem in the elderly. Gastric cancer presents unique challenges in this age group: a distinctive pathological profile, higher incidence of advanced disease, and higher incidence of significant comorbidities that make radical surgical options riskier. Although age alone is not a contraindication for aggressive surgical and adjuvant therapy, the preponderance of the evidence suggests a tailored approach to this disease in the elderly, with radical surgery and aggressive adjuvant and/or neoadjuvant therapy reserved for patients with good performance status, and less radical surgery and adjuvant therapy for debilitated patients with multiple concomitant comorbidities.

Chapter 63

Small Bowel Obstruction in the Elderly

Kelley A. Sookraj and Wilbur B. Bowne

Introduction

Small bowel obstruction (SBO) is a common surgical entity that can occur at any patient age. Although the general principles of diagnosis and treatment of SBO has remained consistent across all age groups, recent shifts in both incidence and etiology among patients of more advanced years now requires focused treatment considerations [1]. Historically, the classical dilemmas associated with management of SBO has remained steadfast for the elderly and include (1) differentiating strangulated from nonstrangulated SBO; (2) delineating ileus from SBO; and (3) determining optimal duration of nonoperative management for partial SBO. Indeed, a better understanding and approach to these clinical scenarios is especially pertinent for the elderly due to their increased risk for perioperative morbidity and mortality [2].

To date, no current data suggest much change in the primary etiologic causes of SBO which remains adhesions, neoplasms, and hernias [2, 3]. Likewise, standard operative management still includes an “open” exploratory approach along with adhesiolysis, herniorraphy, enteric by-pass, and/or bowel resection. Similarly, laparoscopic surgery, yet still a promising alternative, remains controversial. Importantly, advances in clinical imaging (e.g., multidetector computed tomography or MDCT) and biotechnology now provide more effective modalities for accurate detection along with preventative measures for reducing recurrence of SBO following major abdominal surgery; ultimately leading to better patient management and outcome.

This chapter will focus on fundamentals for approaching the assessment and timely management of SBO in the geriatric population. Operative vs. nonoperative management in the elderly will be addressed. This review will also highlight the important pathophysiology of adhesion formation and

resultant SBO as well as current data supporting selected minimally invasive approaches for the treatment of this disease. Moreover, operative intervention coupled with recent developments in preventative measures, e.g., biological barriers, will be discussed. Throughout, an algorithmic, evidence-based approach for the evaluation and appropriate therapeutic management will be emphasized.

Epidemiology

Geriatric persons are now the largest growing segment of our population, with the number of persons 65 years of age and older more than doubling by the middle of this century, to approximately 80 million [4]. What remains problematic is accurately determining the actual incidence of SBO among this cohort. Previously, patient statistics were typically derived from population-based samples, primarily through national hospital-based discharge registries predicated upon imprecise coding schema for SBO; now seemingly more standardized in the updated International Classification of Diseases (ICD-10 CM) [5]. Therefore, current data likely reflect an underestimation of this escalating clinical problem.

Nevertheless, recent trends in aging have shown that patients 65 years of age and older make up 38% of all hospital discharges accounting for nearly 43% of in-patient care days [4]. These rising figures remain in accord with overall age-adjusted national rates of hospitalization for intestinal obstruction occurring in 44.8 per 10,000 [4]. Similarly, census data based upon National Health Statistics for 2008 report an increasing rise in intestinal obstruction with advancing age (see Fig. 63.1) [6]. These upward trends remain in accord with previously published data derived from state hospital-based discharge registries correlating age-specific increases of SBO with gender, whereby females (age > 75 years) had a greater predilection (Fig. 63.2) [7], in part, attributed to a larger number of operative procedures performed on woman, both abdominal and gynecologic.

FIGURE 63.2 Data derived from state-based discharge registries show that as age increases, so does the incidence of obstruction, with women having an increased predilection with age. National Center for Health Statistics, 2004.

FIGURE 63.3 Rate of age-specific reported procedures (lysis of adhesions) performed following a diagnosis of small bowel obstruction. National Health Statistics Report, No. 5 pp. 1–20, 2008.

Moreover, as small bowel obstruction increases with age, so also does the rate of reported operative procedures (lysis of adhesions, only) performed on elderly patients (Fig. 63.3) [6]. However, more concerning is recent data on the actual incidence of intestinal obstruction (without mention of

hernia) derived from the National Center for Health Statistics; demonstrating US age-specific death rates from SBO being more likely to occur in the elderly; especially among individuals over age 70 (Fig. 63.4) [7].

Etiology-Specific Considerations in the Elderly

To predict the etiology of SBO and direct its treatment, it is first useful to classify SBO using several defining characteristics. Upon initial presentation, the degree of luminal obstruction should be described as either partial or complete. Equally important is *where* along the axis of the small bowel does the obstruction occur (e.g., proximal, mid, or distal). Underscoring the importance of these descriptors is the clinical scenario of the worrisome “closed” loop obstruction where two areas of complete obstruction prevent axial flow of intestinal contents from the involved bowel loop in either the aborad or orad direction. Similarly, structures causing obstruction can also be classified by their anatomic location as they relate to the perpendicular axis of the bowel. These structures may be either extrinsic and/or intrinsic to the bowel wall [8–10], both capable of comprising the entire lumen – as seen in obturation obstruction. Table 63.1 depicts some of the more common etiologies for SBO, keeping in mind that increasing age is a risk factor for most [11].

By definition, mechanical bowel obstruction is an abnormal decrease in the caliber of the involved bowel such that the passage of liquid or solid intestinal contents is impeded. In the majority of cases, SBO starts out as a simple mechanical obstruction with adequate blood supply to the intestinal wall such that the bowel remains viable. However, SBO can progress to strangulation where local bowel ischemia occurs either by direct compression of the affected segment by the obstructing lesion or by extreme dilation and increased

pressure in the bowel just proximal to the obstruction, leading to mesenteric occlusion and diminished vascular perfusion.

By comparison, the etiology and pathophysiology of large bowel obstruction (LBO) is considerably different from those of SBO; due to the mostly retroperitoneal nature of the large bowel, it's relatively short mesentery, along with the competency of the ileocecal valve. Indeed, both types of obstruction occur frequently in the elderly, but nearly 80% of intestinal obstruction involves the small bowel; the predominant cause of obstruction in the elderly being due to adhesions from prior abdominal surgery [12]. Thus emphasis of this chapter will focus on the pathophysiology, management, and measures to prevent intra-abdominal adhesions. Figure 63.5 illustrates the incidence of the three most common causes of SBO in the elderly – postoperative adhesions, neoplasms, and hernias – again all have increasing prevalence in the elderly population [10].

Adhesions

More than 90% of abdominal adhesions develop after surgery [13, 14]. The formation of adhesive bands following surgical manipulation is a dynamic process that can occur within several days after surgically traumatized tissues appose one another. Under *normal* circumstances, following nonsurgical traumatic injury, an inflammatory response ensues with recruitment and release of pro-inflammatory cells and cytokines (e.g., interleukin-1) along with activation of the coagulation cascade resulting in the deposition of a fibrinous matrix between apposing tissue surfaces. This fibrin matrix consists primarily of polymorphonuclear cells (PMNs), macrophages, eosinophils, red blood cells, platelets, and tissue debris encased within fibrinous strands. In most cases, such an *early* fibrin matrix is temporary and undergoes fibrinolysis following activation of tissue plasminogen; whereafter degradation occurs within 72 h leading to tissue remodeling and repair as mesothelial and mesenchymal cells proliferate to restore peritoneal defects. This process occurs 4–5 days after tissue injury preventing permanent attachment of adjacent tissue surfaces. In contrast, following surgically induced trauma, these involved tissues become ischemic from reduced blood flow resulting in suppression of fibrinolytic activity. With an absence of fibrin degradation (days 5 through 7), the fibrinous matrix now matures into an adhesive band from continued deposition of collagen and organization by fibroblasts. Over time, these adhesive bands represent a well-organized composition of connective tissues containing arterioles, venules, capillaries, and nerve fibers.

Remarkably, postoperative adhesions account for approximately 60% of all cases of intestinal obstruction in the elderly since many patients by the age of 65 have already undergone some form of abdominal surgery [15]. Whereby, the remaining causes of adhesions are typically secondary to inflammatory processes: such as pelvic inflammatory disease, diverticulitis, tuberculosis, and peritonitis.

The onset of adhesion-associated SBO may occur from several days up to 65 years from the initial operation. However, most SBOs develop earlier on during this interval period with reported median times to occurrence between 1.5 and 5.0 years [16–18]. Interestingly, the incidence of SBO after abdominal surgery appears to decrease over time; however, the cumulative risk remains substantial over the increasing lifetime of the patient. Nieuwenhuijzen et al. reported on a series of 234 patients who underwent colectomy and found that 11% of patients developed SBO within the first postoperative year and 30% within the first 10 years [19]. Similarly, a series from Norway demonstrated a 9% cumulative incidence of SBO after colorectal resection over 5 years [20].

Associated procedure-related formation of adhesions typically results after colorectal procedures, appendectomies,

as well as multiple prior abdominal surgeries (including adhesiolysis for SBO) each accounting for 20–25% occurrence of adhesive SBO. Gynecologic procedures comprise the remaining 10–15% [18, 21, 22]. These procedures have been found to lead to the formation of single and multiple matted adhesive bands. Interestingly, vascular procedures have also been found to contribute substantially to the occurrence of adhesive SBO [23–25]. Therefore, not surprisingly, more than half of all adhesions causing SBO typically involves the ileum and occur within the pelvis. Moreover, in a recent Mayo Clinic series report, 48% of adhesion-associated SBO resulted from only single bands, whereas nearly 40% were multiple, among these 10% were categorized as dense [16]. In part, these findings clearly support adopting a less traumatic surgical approach (e.g., laparoscopy) in the treatment of certain diseases.

Neoplasms represent the second most common cause of SBO and are responsible for nearly 20% of intestinal obstruction in the elderly. Malignant obstruction occurs by the following mechanism (s): (1) via direct tumor extension causing extrinsic compression of bowel, (2) bulky lymphatic metastases which impinge on adjacent bowel, (3) and, more commonly, peritoneal implants (e.g., carcinomatosis); typically ovarian in origin, leading to a large burden of peritoneal disease and SBO [10]. Tumors intrinsic to the bowel wall, such as carcinoids or lymphomas, do occur and can cause obstruction, although this is extremely uncommon.

The third most common etiology found in the geriatric population is derived from hernias, which accounts for the remaining 10% of cases of SBO. Clinically, hernias are more often associated with bowel strangulation than adhesive bands [8]: these include ventral, umbilical, incisional, inguinal, and internal hernias. In addition, there are certain hernias that occur more frequently in the elderly, also requiring special consideration if a diagnosis of hernia-associated small bowel obstruction is suspected; these include femoral and obturator hernias. There is a well-known preponderance of femoral hernias among female patients, therefore a high incidence of suspicion is warranted and femoral hernias should never be overlooked. By comparison, obturator hernias, however less common, should also be considered in the aging population with chronic disease, also more prevalent in the elderly and often associated with bowel strangulation [10].

Other miscellaneous causes of small bowel obstruction (10%) in older patients include inflammatory disease processes; such as Crohn's disease, diverticulitis, and radiation-induced colitis. Moreover, gallstone ileus which is rare in the general population, is more common in the elderly and can lead to SBO. Volvulus, bezoars (particularly in edentulous patients with prior gastrectomy), foreign bodies, fecal impaction, intestinal wall hematomas from blunt traumas (i.e., traumatic falls), and intestinal wall abscesses are also potential causes of small bowel obstruction in the elderly. Clinicians must be aware of these possibilities when differentiating an underlying cause for small bowel obstruction.

Moreover, as minimally invasive techniques become a larger part of our diagnostic and treatment armamentarium, application of these techniques is likewise expanding in the elderly due to the potential advantages for reduced morbidity. However, with these changes, new etiologic subclasses of iatrogenic causes of SBO are now being reported with increasing frequency. For example, endoscopically placed foreign objects, such as percutaneous endoscopic gastrostomy tubes [26–28] and endoscopic retrograde cholangiopancreatography (ERCP) stents [29–31], can become dislodged and lead to obturation obstruction. Similarly, SBO after laparoscopic procedures is well established [32]. Hernias can occur in trocar sites as well as through peritoneal defects created during laparoscopic procedures [33, 34]. Although postoperative adhesions are less likely, they also can occur. Because of the different etiologies of obstruction after laparoscopy, the general approach to SBO after laparoscopy may differ from that after laparotomy. One recent report examining a series of patients with early postoperative SBO after laparoscopy found that all patients eventually required surgical intervention [35].

Pathophysiology of SBO and Evaluation

Mechanical small bowel obstruction, (e.g., adhesion, neoplasia, and hernia) is accompanied by proximal intestinal distension which is a result of the accumulation of normal gastrointestinal secretions and gas above the obstructed segment. Initially, hyperperistalsis of the bowel is stimulated from intestinal distension leading to frequent loose bowel movements distal to the point of obstruction. Typically, this occurs in the early onset both in partial and complete obstruction. Paradoxically, presentation of frequent bowel movements in the elderly has been found to contribute to high rates of misdiagnosis, delayed treatment, and resultant increased morbidity and mortality [36–38].

As the distension becomes more severe, intraluminal hydrostatic pressures increase leading to the compression of the intestinal mucosal villus lymphatics. This results in the hindrance of lymphatic flow and development of bowel wall lymphedema. Consequently, the venules of the capillaries become congested from the increased hydrostatic pressure at the level of the capillary bed. Resultant fluids accumulate intraluminally as luminal pressures exceed 20 cm H₂O thereby inhibiting absorption and stimulating secretions of salt and water into the lumen, proximal to the obstruction. Moreover, other causes of accumulation of intraluminal fluid may include (1) release of endocrine and paracrine substances, (2) changes in mesenteric circulation, (3) luminal release of bacterial toxins and (4) excess release of prostaglandins. These may all contribute to promoting small bowel epithelial secretion, therefore, inhibiting absorption [36–38]. As a result, loss of intravascular fluid into the bowel manifests clinically

as dehydration and hypovolemia. Consequently, prolonged dehydration can result in oliguria, azotemia, hemoconcentration, and eventually hypotension and hypovolemic shock. Furthermore, congested loops of bowel may twist upon themselves and accompanying mesentery resulting in vascular occlusion. In turn, bowel ischemia and necrosis develop and if untreated perforation, peritonitis, and sepsis may occur.

In general, the pathophysiologic changes that occur in small bowel obstruction are similar between the nongeriatric and geriatric patient population. However, and very importantly, as a result of inherent comorbidities found in the elderly, any delay in diagnosis may negatively impact on patient outcome with mortality exceeding 20% [11].

Clinical Features of SBO in the Elderly

Symptoms of SBO are primarily determined by the anatomic level and degree of obstruction. These include nausea and emesis, abdominal distension, abdominal pain, and obstipation (lack of passage of stool or flatus). Proximal SBO is characterized by frequent vomiting of bilious material and dehydration early in the course of disease with relatively little abdominal distension. With distal SBO, swallowed air and gastrointestinal secretions leads first to small bowel and abdominal distension. Only later do patients develop vomiting, usually after bacterial overgrowth has resulted in a feculent character to the enteric content. Partial obstruction is accompanied by continued, though potentially diminished, passage of flatus or stool. Early complete obstruction may also be accompanied by seemingly normal bowel movements, but eventually obstipation occurs.

Strangulation is notoriously difficult to detect reliably. Classic signs include fever, tachycardia, hypotension, and severe pain or focal tenderness which are especially unreliable in the elderly, whereby the inflammatory response may be muted. Similarly, an elevated white blood cell (WBC) count may be absent in the elderly patient. From a previous Mayo Clinic series [16], strangulation was present in 13% of patients operated for SBO and was most commonly seen with the etiologies of hernia and small bowel volvulus. Only 52% of patients with strangulation had an elevated WBC count, and the mean WBC count for patients with strangulation was just 2,000 cells/mm [3] higher than that observed for patients with simple obstruction.

Diagnostic Considerations for the Elderly

Symptoms of SBO are common presenting complaints of elderly patients. The differential diagnosis for abdominal pain, nausea, and vomiting includes gastroenteritis, food

poisoning, pancreatitis, biliary colic, porphyria, diabetic ketoacidosis, intestinal ischemia, constipation, paralytic ileus, and intestinal pseudo-obstruction. Compounding this problem in the elderly are age-related concurrent comorbidities that have been shown in a recent large retrospective study to be attributed to misdiagnosis, delay in surgical evaluation, and increased mortality [39]. Among these diagnoses, SBO is fairly common. In a review of ER visits to a regional trauma center by patients over 65 years of age, 12% of patients presenting with nontraumatic abdominal pain were ultimately found to have SBO [40]. Patients should be asked about any history of abdominal surgery or SBO; and during the physical examination, evidence of abdominal wall hernias should be vigilantly elicited. Laboratory values that can aid in the diagnosis and management of these patients include a complete blood count (CBC), basic metabolic profile, and serum amylase. As the classic signs of strangulation are often absent in the elderly, a leukocytosis, elevated hematocrit, and blood urea nitrogen (BUN) levels are often seen as a consequence of dehydration. Serum bicarbonate may be elevated because of loss of chloride-rich emesis and as part of a contraction alkalosis. These findings indicate a significant fluid deficit, which should be aggressively corrected upon initial presentation.

Diagnostic imaging is an important part of the evaluation of every patient with suspected SBO. Supine and upright abdomen and upright PA chest films are typically all that is required to confirm the diagnosis of complete SBO and to plan its treatment. Dilation of small bowel, paucity of colon and rectal gas, and air-fluid levels suggest complete SBO. Forty eight percent of patients with proven SBO will have abdominal plain films that are consistent with SBO [16]. This, of course, means that almost half of patients with SBO have equivocal or even normal plain films, with residual colonic or rectal gas.

When these films are not diagnostic of complete SBO, the decision has traditionally been to rely on the clinical examination and serial plain films. In our experience, as well as other CT scans has been useful in equivocal cases as an early diagnostic test [41] and alters management in up to 20% of patients [42]. Some centers have reported high accuracy of CT in identifying strangulation obstruction. A prospective evaluation of CT in 60 patients with high-grade SBO (with 48% strangulation rate) showed that CT had 100% sensitivity and 61% specificity for detecting bowel ischemia [43]. The CT findings consistent with strangulation included bowel thickening and a high attenuation bowel wall on non-enhanced CT and abnormal bowel wall enhancement and mesenteric fluid on enhanced CT. A similar series of 100 patients from a different institution found a sensitivity of 83% and a specificity of 93% [44]. In contradistinction to these studies, several studies have compared CT with plain radiography and have found only modest differences in the overall accuracy of these tests when evaluating the grade of

obstruction [45, 46]. CT also is helpful in patients with closed loop obstructions and patients who swallow little air and thus have a gasless proximal bowel, as these problems are difficult to detect on plain films. At our institution, contrast-enhanced CT scans are not routinely used in the decision-making process except when the clinical history, physical examination, and plain films are not conclusive for a SBO diagnosis.

In our experience, CT scans are more likely to demonstrate the cause of SBO, particularly when the obstruction is not secondary to adhesions. Current generation multidetector computed tomography or MDCT now permit high-quality reformatted images to be obtained in multiple planes which facilitate identification of the transition point and other findings in SBO: presence of a high degree of SBO and abnormal vascular course around the transition zone. Ultimately, MDCT may result in a paradigm shift toward earlier cross-sectional imaging in the elderly by its inherent ability to better predict the necessity for emergent surgery (i.e., ischemia) in the elderly when SBO is caused by adhesions [47, 48].

Less often used diagnostic imaging modalities in the acute setting include ultrasonography [49–52] and MRI [53]. In the more subacute and chronic setting in patients with an intermittent or partial SBO, enteroclysis (small bowel enema) and small bowel follow-through may be useful [54, 55]. The passage of water-soluble oral contrast into the cecum within 4 h after CT or small bowel follow-through, remains highly predictive of nonsurgical resolution of SBO [56, 57]. Interestingly, there have also been two randomized controlled trials examining whether water-soluble contrast speeds the resolution of partial SBO. Assalia et al. found a therapeutic benefit in terms of a shorter hospital stay in those patients receiving oral contrast with SBO from a variety of etiologies [58], whereas Feigin et al. reported no therapeutic benefit in patients with postoperative SBO [59].

A special case of the diagnostic dilemma between SBO and paralytic ileus may occur during the early postoperative period. At 1–6 weeks after abdominal surgery, inflammatory adhesion can be thick and highly vascular. For these reasons, the morbidity of reoperation can be considerable. Because these early adhesions are also in a fluid state of constant remodeling, there is also a good chance of resolution of even high-grade partial obstructions without surgical intervention. It therefore becomes even more critical to define the degree of obstruction in these patients to avoid the higher morbidity of reoperation. In such circumstances, MDCT scanning may prove more beneficial for accurately distinguishing these equivocal cases [47, 48]. In very selected cases, when persistent partial SBO is a problem, endoscopic placement of a long intestinal tube may prove to be therapeutic and allow for a high-quality small bowel contrast study that more clearly characterizes the site of partial obstruction.

Initial Treatment

Surgery, like aviation, in itself is not inherently dangerous. But to an even larger degree than the air, it is terribly unforgiving of any carelessness, incapacity or neglect.

Peter K. Kottmeier, M.D., Chief of Pediatric Surgery, SUNY-HSCB (1965–1999)

Inscribed on the entrance of the Peter K. Kottmeier Library, SUNY-HSCB

The traditional adage of “never let the sun set or rise on a small bowel obstruction” [16], in part, underscores the severity of this diagnosis, particularly in the elderly. Recently, however, this has been largely modified by a multifactorial assessment and approach that first considers the physiologic abnormality that has occurred since the onset of the SBO (i.e., hemodynamic status), type of SBO (partial, complete, strangulated), and patient comorbidities/performance status (cardiac, pulmonary, renal, malignancy).

Even the patient who clearly has a complete bowel obstruction benefits from initial nonsurgical measures including proximal decompression, aggressive fluid resuscitation, and correction of electrolyte abnormalities. A Foley catheter is critical in the elderly to assess organ perfusion and fluid status. Generally, a nasogastric tube is adequate to decompress the gastrointestinal (GI) tract, but in some patients in whom a prolonged course of nonoperative management is contemplated, as for early postoperative SBO or the patient with multiple previous laparotomies or known severe adhesions, a long nasointestinal tube may be considered.

Patients with complete SBO or with obvious signs of strangulation should be expeditiously resuscitated and then brought to the operating room. This strategy particularly applies to patients in whom the etiology is thought unlikely due to adhesions or neoplasm. In this case, *not letting the sun rise or set*, certainly applies. However, most patients admitted for an SBO do not fall into this category. Two-thirds to three-fourths of patients with partial (primarily adhesive) SBO can be treated conservatively, with resolution of their acute episode [60–63]. In patients with a partial SBO, the duration of medical therapy continues to be a hotly debated issue. Recent series examining this question have consistently shown that partial SBOs that ultimately resolve generally do so within 24–72 h. Delays beyond 48 h have been associated with increased morbidity in some series [63], whereas others have shown no increased morbidity with even longer delays [64].

The potential arguments against maintaining a nonoperative approach are that the diagnosis of strangulation is inaccurate [65] and the duration of medical treatment may be proportional to the incidence of strangulation or need for bowel resection and the subsequent higher incidence of complications. These concerns are particularly relevant in elderly patients. Adhesive SBO requiring surgery in elderly patients ultimately requires bowel resection in up to 50% of

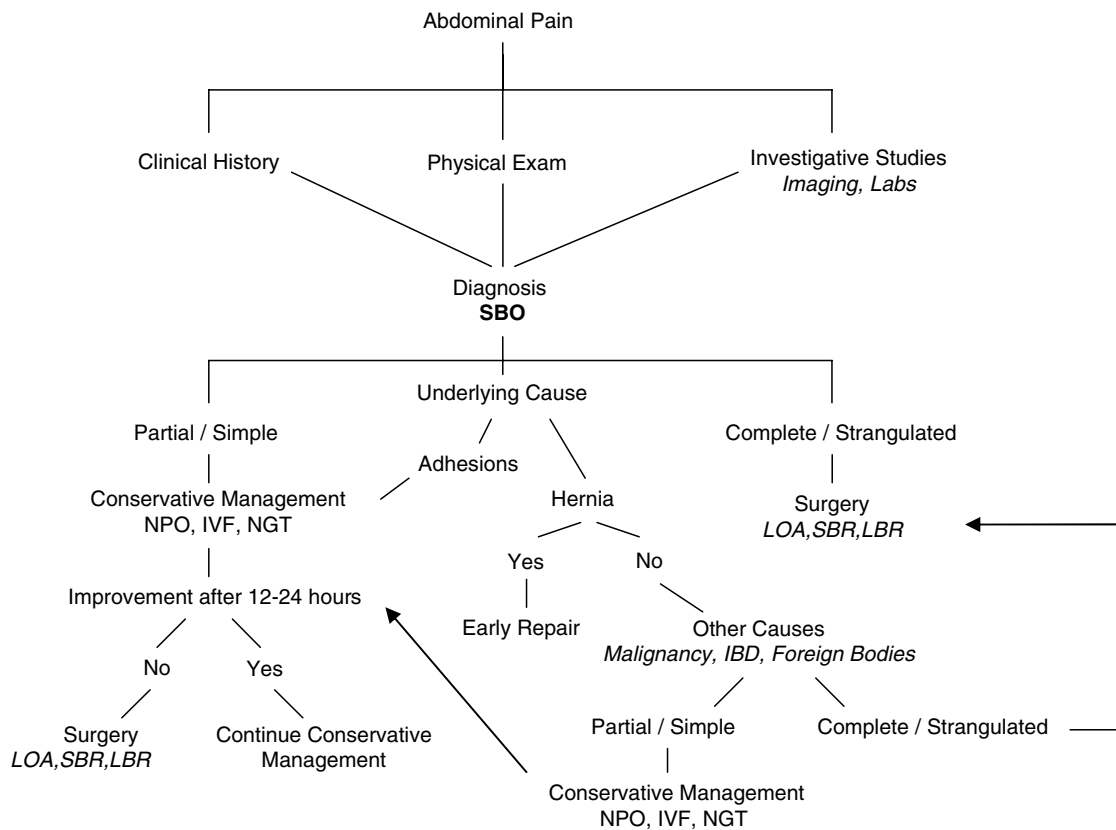

FIGURE 63.6 Algorithm for management of small bowel obstruction in the elderly. *SBO* small bowel obstruction, *IVF* intravenous fluid, *NGT* nasogastric, *LOA* lysis of adhesions, *SBR* small bowel resection, *LBR*

large bowel resection, *NPO* nil per os (nothing by mouth), *IVF* intravenous fluids, *IBD* inflammatory bowel disease.

cases [66], whereas only 8% of patients of all ages required bowel resection in the Mayo Clinic series [16]. In that series, among patients in whom strangulation was found, delays of more than 4 h from presentation to surgery were associated with higher morbidity rates. Much emphasized is the importance of the underlying etiology when determining the mortality risk of delayed surgical intervention [16]. Data from the Mayo Clinic series showed that in the case of obstruction due to hernia, the time from presentation to operation was directly related to the mortality rate, but this relation with mortality did not exist for SBO caused by adhesions or malignancy.

We favor a selective approach in the elderly patient with SBO. The immediate strategy should be determined by consideration of (1) the evidence for current bowel ischemia and (2) the presumed etiology of the SBO and degree of obstruction. Patients with two or more signs of strangulation, radiographic signs of complete SBO, or both are operated on as soon as possible after adequate resuscitation is carried out. Nasogastric decompression and serial examinations are then planned for those in whom an adhesive SBO is likely. For those in whom the diagnosis of SBO is unclear or the etiology is in question, CT is performed. The longer-term strategy in patients initially treated nonoperatively should include both the above factors as well as (3) the likelihood of intraopera-

tive and postoperative complications. These factors should be weighed against the likelihood of success using continued nonsurgical management. Figure 63.6 shows our diagnostic and treatment algorithm for patients with SBO.

Surgical Treatment: General Principles

Preoperative antibiotic coverage to cover enteric organisms should be administered, as a number of cases involve bowel resection or inadvertent enterotomy. Although elderly patients are more likely to have underlying cardiovascular disease, increasing the risk of a perioperative cardiac event, invasive monitoring devices are rarely required. Hypotension upon induction of anesthesia should be avoided by attention to adequate preoperative fluid resuscitation often requiring 3–4 L of intravenous isotonic crystalloid.

Laparotomy should be performed through a midline approach with at least part of the initial incision over virgin skin, if possible. Entry through the fascia is done with extreme care, avoiding the use of cautery, as transmitted heat can injure underlying bowel. Adhesions are usually stronger than the junctions between the small bowel muscle layers

and the muscularis propria and submucosa, and this seems particularly true in the elderly patient. Sharp dissection with scissors or knife should therefore be performed to avoid seromuscular injuries. We generally lyse adhesions from the anterior abdominal wall first and then proceed to run the small bowel lysing adhesions as we progress from the terminal ileum to the ligament of Treitz.

While running the bowel, the etiology of the SBO and local bowel viability are assessed. The commonly available parameters include bowel color, peristalsis, and mesenteric pulsations. Although clearly viable and clearly nonviable extremes are easy to identify, many gradations of color are difficult to judge, and assessment of ultimate viability is prone to error. Adjuncts to these methods continue to include Doppler flow probe assessment of mesenteric and antimesenteric blood flow [67, 68], intravenous fluorescein perfusion [67, 69], and electromyography (EMG). Although these methods have their advocates, none has consistently been shown to have higher accuracy than “clinical judgment” using visual and manual inspection. Our general strategy is to resect questionable bowel if possible. If resection would result in less than 4–5 ft of clearly viable intestine, questionable segments with the highest likelihood of viability should be left in situ with a planned “second-look” reoperation within 24–48 h.

To allow abdominal wall closure, frequently the bowel must be decompressed. This can be achieved with a long nasointestinal tube, but we favor gentle retrograde milking of the intestine toward the duodenum with fluid evacuation via a nasogastric tube. To minimize excessive distension and the risk of serosal tears, this process is first started in the mid-jejunum. The proximal jejunal segment is then evacuated of luminal content. The process is then repeated starting progressively more distally on the bowel. Prior to closing the abdomen, the bowel loops should be laid back in the abdomen in gentle folds. Some have advocated the use of long intestinal tubes to act as stents, particularly in the patient with recurrent SBO or pervasive adhesions [70]. Another option gaining popularity is the application of hyaluronidase-containing films to inhibit adhesion formation [71]. Clinical trial data (see section “Biological Barriers”) demonstrate safety and potential efficacy for reducing adhesions and adhesion-associated SBO.

Laparoscopic Treatment of SBO

Laparoscopic surgery has theoretic advantages over open surgery including decreased postoperative pain, reduced wound complications, decreased respiratory complications, and shorter hospital stay. These advantages are particularly attractive in elderly patients and have likely led to a decreased

threshold for elderly patients seeking surgical management by a minimally invasive approach. Thus far the laparoscopic approach to SBO has not been widely accepted, although recent reports of SBO management using a laparoscopic approach have been documented [72–76]. The challenge for laparoscopy for treating SBO rests not in the diagnostic efficiency which is between 60 and 100%, but the therapeutic efficacy which is generally low (40–88%). Not surprisingly, the conversion rate to laparotomy has been reported to be as high as 52%.

Several factors make laparoscopic treatment of SBO difficult and have prevented many surgeons from adopting this approach to SBO. Exposure can be problematic because of diffuse adhesions to the anterior abdominal wall and because distended bowel may have already increased the intra-abdominal pressure and decreased the volume of pneumoperitoneum that can be achieved. Therefore, it is generally best to use an open insertion technique and to select an initial insertion site remote from previous scars. Bowel distension should be minimized by preoperative nasogastric decompression, and in selected cases using a long intestinal tube prior to attempting laparoscopic treatment. Perhaps the most common reason for reluctance to use laparoscopy for SBO is a concern that treatment may ultimately require an extensive adhesiolysis or resection that is problematic to achieve laparoscopically. Therefore, proper patient selection is paramount before choosing a minimally invasive approach. A recent Medline, Embase, Cochrane review from 1980 to 2007 identified predictive factors for a successful laparoscopic adhesiolysis which includes: ≤ 2 previous laparotomies, adhesions associated with appendectomy, single adhesive band, early < 24 h laparoscopic management from onset of symptoms, no peritonitis, and surgical expertise [73].

The laparoscopic approach is particularly attractive for adhesive SBOs where there is a single adhesive band. Conventional laparotomy is recommended for malignant SBOs and hernia-related SBOs, where there is a high rate of strangulation. The general principles of the laparoscopic approach are similar to those of the open approach. Adhesions are dissected sharply, and after adhesiolysis the bowel is inspected from the ileocecal valve to the ligament of Treitz.

Although one-half to two-thirds of patients may be treatable laparoscopically, one must anticipate a high conversion rate to open laparotomy; moreover, the mastery of laparoscopic skills is essential. A study by Bailey et al. compared SBOs treated in two surgical units, one with a special interest in laparoscopy [77]. The laparoscopy unit attempted laparoscopic treatment in 80% of SBOs, and among those cases, they completed treatment laparoscopically in 56%. The laparoscopically treated patients left the hospital 5 days earlier than the open procedure patients, but they also had a higher rate of unplanned reoperation (14% vs. 5%).

In 2010, the safety and efficacy of diagnostic laparoscopy for SBO appears well established from retrospective studies, whereas laparoscopic adhesiolysis requires careful patient selection with an operative plan that includes converting to an open approach if extensive adhesions or nonadhesive causes are encountered. Ultimately, prospective randomized trials assessing all clinically relevant outcomes are needed.

Outcomes of Treatment of SBO

Most studies of the outcomes of treatment of SBO have centered on traditional surgical outcomes, such as perioperative mortality, survival, and postoperative complications. Increased age is a risk factor for mortality from SBO (Fig. 63.4). Perioperative mortality is also related to the etiology of the SBO. For example, SBO with a malignant etiology has an in-hospital mortality of 21% and a median survival of 6 months compared to a 4–5% mortality risk for hernia and adhesive etiologies. Similarly, a large prospective experience by Miner et al. from Memorial Sloan Kettering [78] showed that the potential benefits of palliative surgery are minimized by the inherent morbidity (29%) and mortality (11%) of these procedures. Of note, delay from symptom onset to presentation is not generally related to mortality risk except in the case of hernias, where there is also a higher risk of strangulation; overall in-hospital morbidity is 30% but is increased in patients with strangulation to 60%.

As adhesions represent the most common cause of SBO in the elderly, identifying pertinent risk factors for adverse outcome following surgery for adhesion-associated SBO may provide the clinician with important information for stratifying the risk-to-benefit ratio for clinical decision making especially in the more concerning elderly population. A recent VA National Surgical Quality Improvement Program developed a morbidity and mortality risk index assessment based on a cumulative score that predicts the probability of an adverse outcome [79]. Not surprisingly, the odds of mortality in a patient 70–79 years of age are increased by a factor of 1.855 compared to a patient younger than 50 years. Similarly, better outcomes are associated with adhesiolysis only, compared to bowel resection.

Attempts were also made to ascertain the longevity of treatment of SBO. Specifically, for patients treated nonsurgically, the likelihood and timing of recurrence, and how this compares to patients treated surgically? These questions were largely addressed from a state-wide longitudinal population-based outcome analysis derived from 32,583 hospitalized patients (mean age 63 years) admitted with a diagnosis of SBO (index admission). From this study, Foster et al.

[63], showed that in California, from data derived from patients hospitalized in 1997, SBO was primarily managed nonoperatively in 76% of these patients. Of the patients that underwent operative management (24%), there was a longer length of stay, lower mortality rate, fewer SBO readmissions, and longer time to readmission. In general, patients who did not have operations were usually older and with more comorbidities. However, regardless of the treatment, 81% of patients had no subsequent SBO requiring readmission over the 5-year study follow-up period. Similarly, Landercasper et al. [80] retrospectively reviewed 309 consecutive patients with SBO and followed them for recurrence [55]. The SBOs recurred in 34% by 4 years and in 42% by 10 years. Those who were operated on had a lower recurrence rate (29%) than those who were treated nonoperatively (53%). Among those who had surgery, recurrences differed by etiology: malignant (56%), adhesive (28%), and hernia (0%). In this study, the number of prior obstructive episodes was not a risk factor for recurrence. However, Fevang et al. [81] retrospectively studied 500 patients with adhesive-associated SBO (ASBO) for up to 40 years for recurrence [56]. They found that the cumulative recurrence rate for patients operated once for ASBO was 18% after 10 years and 29% at 30 years. The likelihood of a recurrent ASBO was highest within 5 years after the previous one, but a considerable risk was still present 10–20 years after an ASBO episode.

In addition to recurrence risk, treatment choice affects the cost of care and utilization of health-care resources. The costs of caring for patients with SBO are considerable. From a Swedish study, 60% of all bowel obstructions were due to adhesions; 65% of them required more than a 1-day hospital stay, and 45% of these required surgery. Calculating direct costs and extrapolating these data, \$13 million are spent on adhesive SBO in Sweden (a country of 8.5 million population) annually [82]. In many cases, treatment choice is determined solely by the initial clinical presentation. Either the decision to undergo surgery occurs early or an initial short duration of medical management results in rapid clinical improvement and resolution of the SBO. However, in patients with high-grade partial obstruction likely due to adhesions, an early decision to treat surgically is likely to have a favorable clinical outcome but may result in a longer hospital stay and higher cost of care compared to a nonsurgical approach. As one might expect, retrospective analysis of patients treated medically and surgically show that surgically treated patients have clinical outcomes similar to those treated medically but with longer lengths of stay [17]. The additional costs of care in patients ultimately treated surgically may be as much as eight times higher than nonsurgically treated patients. This differential makes tests with improved diagnostic accuracy such as CT or MDCT more cost-effective for questionable partial SBO [83].

Biological Barriers

Barriers are biosynthetic membranes or gels that have been shown to be effective in decreasing surgically induced adhesions. One of the first prototypes that was successful in reducing postoperative adhesions in humans was Interceed® which was composed of modified oxidized regenerated cellulose. This particular barrier was found to be applicable following gynecologic procedures; however, its use in general surgical procedures is unknown. Another type of biological barrier is expanded polytetrafluoroethylene (PTFE). This was shown to prevent pelvic adhesions. However, PTFE was not cost-effective or bioabsorbable and required a large piece of material and suturing to keep it in place for adhesion prevention.

To date, the most efficacious barrier is a hyaluronan and carboxymethylcellulose bioresorbable membrane called Seprafilm®. The mechanism of action of adhesion prevention is believed to occur by one of the components known as sodium hyaluronate. It is believed to improve peritoneal healing by increasing the proliferation of mesothelial cells and facilitating their detachment and migration thereby leading to the restoration of the mesothelial lining within the peritoneal cavity. It is also thought to increase the fibrinolytic response of mesothelial cells which may aid in adhesion prevention.

Seprafilm® is typically prepared as a membranous sheet that is applied over potential sites of adhesion formation, (e.g., traumatized tissue), prior to closure following an abdominal surgical procedure. Placement of the membrane requires that the peritoneal cavity, as well as the instruments and gloves used to handle the barrier be as dry as possible. Approximately 1–2 cm of the membrane should be exposed from its holder prior to application. When entering the abdominal cavity the membrane can be curved or slightly folded to facilitate placement over the desired area. To ensure adequate adherence to the tissue a dry instrument or gloved hand can be used to gently press down on the membrane. Seprafilm® should be sufficiently placed over the margins of the incision or surgically traumatized tissue and overlapped to achieve sufficient coverage. Importantly, a bowel anastomosis should not be wrapped with Seprafilm® as this practice has been associated with adverse events. Seprafilm® slowly resorbs within 7 days of placement and is fully excreted by 28 days.

Seprafilm® was evaluated in a number of prospectively, randomized, controlled, multicenter studies and consistently demonstrated overall safety [84–89] (Table 63.2). The larger clinical trials did show a significant reduction in the formation of adhesions and adhesion-associated SBO [84–89] (Table 63.3). These barriers potentially provide an excellent form of adjunctive therapy for preventing postoperative adhesions which is the number one cause of SBO, not only in the elderly but also in the general population.

^aOverall complication

Summary

Small bowel obstruction is a common pathological process that can occur in any patient population. Its effects, however, are devastating in the elderly and warrants prompt appropriate management. Utilization of a thorough clinical history, physical examination, and investigative studies provide the necessary information to determine a diagnosis and direct the next step in treatment. Immediate aggressive resuscitation is required with monitoring of hemodynamic parameters especially in older patients because of their limited physiologic reserve and comorbidities.

Based on the type of SBO, a trial of conservative management may be initiated or definitive surgery may be performed. Either, the standard open laparotomy or minimally invasive surgical technique may be used dependent on surgeon experience, patient stability or underlying cause. Recent developments of biosynthetic products have made a positive impact in the management of SBO that help in the prevention of surgically induced adhesions in the elderly.

Chapter 64

Lower Gastrointestinal Bleeding in the Elderly

Sylvia S. Kim and Michael E. Zenilman

Introduction

Lower gastrointestinal bleeding is a commonly encountered surgical problem that increasingly affects the elderly. This is not surprising given that the two most commonly cited causes of lower gastrointestinal bleeding, diverticula and arteriovenous malformations (AVMs) have an increasing incidence with increased age. One large population-based study found that the incidence of acute lower gastrointestinal hemorrhage increased over 200-fold from the third to ninth decades of life [1] with an incidence of 500 episodes per 100,000 people per year in the elderly population. Increased age has also been demonstrated to be an independent predictor of both increased length of stay as well as cost of hospitalization in resource utilization studies [2].

The goals of therapy for an elderly patient presenting with a lower gastrointestinal bleed are the same as those for a younger patient: resuscitation and stabilization, localization of the bleeding source, and definitive therapy. However, elderly patients do merit special consideration. Comorbidities are common and can translate into adverse outcomes in elderly surgical patients [3]. Polypharmacy often includes antiplatelet agents such as aspirin or other anticoagulants such as warfarin which may impact the severity of gastrointestinal hemorrhage. Impairments in nutrition, cognition, and functional status may also be present to various degrees and should be considered in the assessment of any geriatric patient.

Etiology

Gastrointestinal changes associated with aging include prolonged intestinal motility, mucosal atrophy, and sequelae of atherosclerosis and decreased splanchnic blood flow.

Diverticular disease and vascular ectasias, both acquired lesions related to aging, account for the majority of cases of lower gastrointestinal bleeding in elderly patients. Other conditions causing intestinal bleeding to which the elderly are predisposed include ischemic colitis and neoplasms.

Diverticula

In most large case series, diverticular bleeding is the leading etiology of lower gastrointestinal bleeding (see Table 64.1) [1, 4–15]. Colonic diverticula are false or pulsion diverticula comprised of mucosa and serosa outpouching in areas where the colonic wall is inherently weaker – at the entrance points of the vasa rectae (see Fig. 64.1). These vessels penetrate through the muscular wall of the colon to supply the colonic mucosa. It is rupture of these vasa rectae that account for diverticular bleeding (see Fig. 64.2). Displacement of the vessel by the enlarging diverticulum and subsequent vessel rupture causes hemorrhage into the diverticulum [16]. Colonic diverticula are quite common in Western societies, affecting at least one half of the elderly population. It accounts for 17–67% of all lower gastrointestinal bleeding (see Table 64.1) and an estimated one third of cases of lower gastrointestinal bleeding in the elderly [8, 11, 17]. The estimated lifetime risk of bleeding caused by diverticular disease ranges between 4–48% [18]. The largest literature review to date, examining over 6,000 cases, placed the estimated risk of significant lower gastrointestinal bleeding from diverticulosis to be 17% [19]. The relative risk for diverticular bleeding is increased for regular users of NSAIDs and acetaminophen [20].

While diverticula are most commonly found on the left colon, they can occur throughout the colon, and there is a greater propensity for bleeding to occur on the right side of the colon [21]. Typically, diverticular bleeding is painless and abrupt in onset. It resolves spontaneously in an estimated 80% of patients [22]. Severity of bleeding can be minimal or massive and life-threatening. Approximately, one third will require blood transfusion and/or invasive evaluation while 5% ultimately require surgical intervention [18].

FIGURE 64.1 Endoscopic view of colonic diverticula. Bowel lumen is visible on the right with wide-mouthed diverticula seen on the left.

Arteriovenous Malformations

Arteriovenous malformations (AVMs), also known as vascular ectasias or angiodysplasias, are degenerative lesions that can occur anywhere in the gastrointestinal tract. They are postulated to be caused by chronic, intermittent, low grade obstruction of submucosal veins leading to dilation and tortuosity of submucosal veins, then venules, capillaries, and finally arteries. Ultimately, as precapillary sphincters lose their competency, small arteriovenous communications form (see Fig. 64.3) [22]. Within the colon, they are more commonly found within the right colon, particularly in the cecum

[23, 24]. It is postulated that the increased wall tension found in the cecum as determined by Laplace's Law explains the greater incidence of cecal AVM [25]. An estimated 15% of all massive lower gastrointestinal hemorrhage is attributed to AVM [26] with case series reporting rates from 2 to 30% (see Table 64.1). More commonly, the bleeding is subacute and stops spontaneously, but with a high rate of recurrence – at least 25% in most series [27].

Colitis

Inflammatory bowel disease has a bimodal peak incidence with a second peak incidence in the seventh decade. Both Crohn's disease and ulcerative colitis can manifest as bloody diarrhea. The incidence of massive lower intestinal bleeding attributed to inflammatory bowel disease varies, ranging from 2 to 34% (see Table 64.1).

Ischemic colitis is a condition characterized by impaired perfusion of the colon, typically at the "watershed" areas of the vascular supply such as at the splenic flexure where the distribution of the superior mesenteric artery and inferior mesenteric artery overlap. It is typically a multifactorial process and predominantly a diagnosis of the elderly. Patients often present with bloody diarrhea and abdominal pain. The diagnosis is often made based on clinical presentation. CT scan may be suggestive of colitis. The definitive diagnosis is often made at the time of endoscopy, where mucosal ischemia is evident. Treatment is often supportive with bowel rest, fluid resuscitation and intravenous antibiotics. Patients who present with pneumoperitoneum or peritonitis are manifesting signs of bowel infarction and necrosis and warrant urgent laparotomy. While bloody diarrhea is a hallmark of ischemic colitis, it is an unlikely source of massive blood loss.

FIGURE 64.2 Acquired colonic diverticula. Increased intraluminal pressure causes herniation of mucosa and muscularis mucosa through inherently weak sites of the bowel wall where vasa recta pierce the muscularis

propria between the teniae coli. Hemorrhage occurs when the vessel ruptures either into the dome or neck of a diverticula.

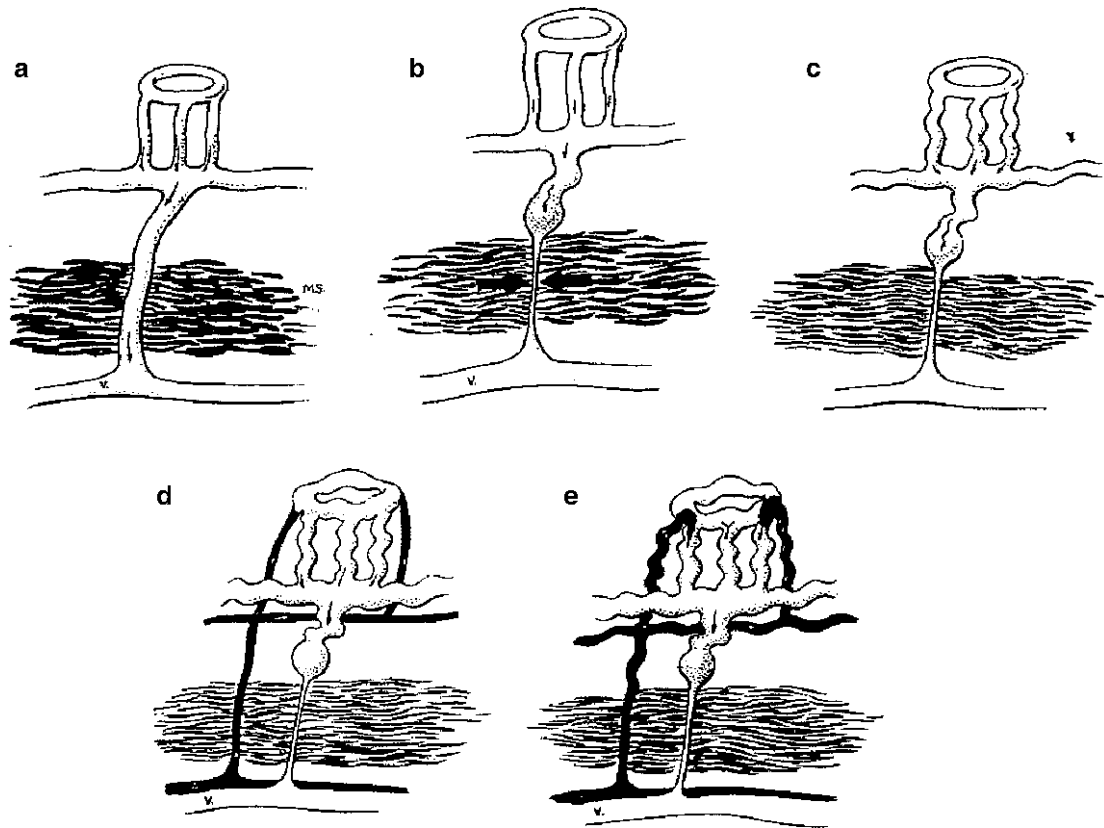

FIGURE 64.3 Proposed concept of the development of vascular ectasias. (a) Normal state of vein perforating muscular layers. (b) With muscular contraction or increased intraluminal pressure, the vein is partially obstructed. (c) After repeated episodes over many years the submucosal vein becomes dilated and tortuous. (d) Later the veins and venules

draining into the abnormal submucosal vein become similarly involved. (e) Ultimately, the capillary ring becomes dilated, the precapillary sphincter becomes incompetent, and a small arteriovenous communication is present through the ectasia. (From Boley et al. [23] with permission).

Neoplasia

Neoplasms typically present with more insidious blood loss and anemia, and do not ordinarily cause major hemorrhage. However, the passage of blood per rectum in an elderly patient, especially in the setting of anemia, needs to be evaluated completely in order to exclude malignancy, even in the presence of more benign anorectal pathology such as internal hemorrhoids. Classically, right-sided colon cancers present with insidious weakness and anemia, left-sided colon cancers present with obstruction, and rectal cancers present with more bright red blood per rectum and sometimes a palpable mass on rectal exam. While massive hemorrhage is uncommon, it can account for up to 2–20% of lower gastrointestinal bleeding (see Table 64.1). It is an important diagnosis to exclude since surgical intervention is often a mainstay of treatment either for curative intent or even in advanced, palliative settings.

Initial Assessment

The fundamental principles guiding the management of acute lower gastrointestinal bleeding remain the same for nonelderly and elderly patients: initial resuscitation, localization of bleeding site, and definitive therapeutic intervention (see Fig. 64.4).

After initial assessment of hemodynamic stability, resuscitation efforts should begin with intravenous fluid resuscitation via large bore peripheral access. A foley catheter is useful in recording strict intake and outtake levels including the urine output – a commonly used indicator of adequate volume resuscitation. Additional monitoring with a central venous pressure (CVP) monitor may be of particular use in the elderly patient. Cardiac function in the elderly is characterized by a number of significant alterations. Both the chronotropic and inotropic response of aged myocardium to adrenergic stimuli are blunted [28]. As a result, both the maximal heart rate and increase in ejection fraction in response to stress are depressed [29]. In addition, due to preexisting comorbidities, the elderly patient may also be taking beta blockers which could impair their tachycardic response to hypovolemia. Older persons are thus more dependent upon preload to maintain cardiac output in the face of increased demand, making them especially sensitive to the dangers of hypovolemia [30]. Adequate fluid resuscitation is therefore of paramount importance in the elderly patient who presents with gastrointestinal bleeding.

An adequate history and physical exam may help in identifying the etiology of the gastrointestinal bleed. In an elderly patient with impaired cognition or memory lapses, communication with the patient's primary physician or geriatrician and family members may provide additional crucial information. An important aspect of the history-taking

is the discovery of use of any anticoagulant or antiplatelet medications. Warfarin toxicity precipitating intestinal bleeding may be amenable to treatment with reversal through transfusion of clotting factors. While NSAID use is more typically associated with upper gastrointestinal bleeding, it can contribute to lower gastrointestinal bleeding as well and has been associated in some series, with an increased need for blood transfusion [31]. History of past episodes of gastrointestinal bleeding from either an upper or lower source should also be elicited. Symptoms such as abdominal pain may be more indicative of an inflammatory process such as ischemic colitis or inflammatory bowel disease. Associated tenderness on physical exam, especially when coupled with leukocytosis on laboratory studies, may warrant further study with imaging modalities such as a CT scan, which are not necessarily considered a standard diagnostic tool in patients presenting with presumed lower gastrointestinal bleeding.

Excluding the possible diagnosis of an upper gastrointestinal bleed is then the next priority in the management algorithm. Brisk blood loss from an upper gastrointestinal source can manifest as apparent bright red blood loss via the rectum in part due to the cathartic effect of the blood itself. Up to 15% of cases of presumed lower gastrointestinal bleeding are actually found to be due to upper gastrointestinal sources [32]. Discriminating between an upper and lower source of bleeding can be accomplished typically either with a nasogastric lavage or upper endoscopy. Biliary, nonbloody nasogastric aspirate typically ensures a lower intestinal source. Nonbiliary aspirates are equivocal and should be further evaluated with upper endoscopy.

Rigid proctosigmoidoscopic or anoscopic evaluation is also recommended to rule out potential anorectal sources. If an anorectal source such as hemorrhoids or anal fissure is found, then management is the same as for the general population. Stable patients with minimal symptoms may respond to conservative management with hydration, fiber bulking agents and stool softeners, since these processes are typically associated with constipation and straining. Actively bleeding hemorrhoids, especially in the face of anticoagulation, may require immediate therapy with either banding ligation or formal hemorrhoidectomy.

Diagnosis and Treatment

Attempts to isolate colonic etiologies of gastrointestinal bleeding typically begin with either a colonoscopic evaluation or tagged red cell nuclear medicine study. Most patients who present with lower gastrointestinal bleeding have stopped actively bleeding by the time they present to the hospital for further evaluation.

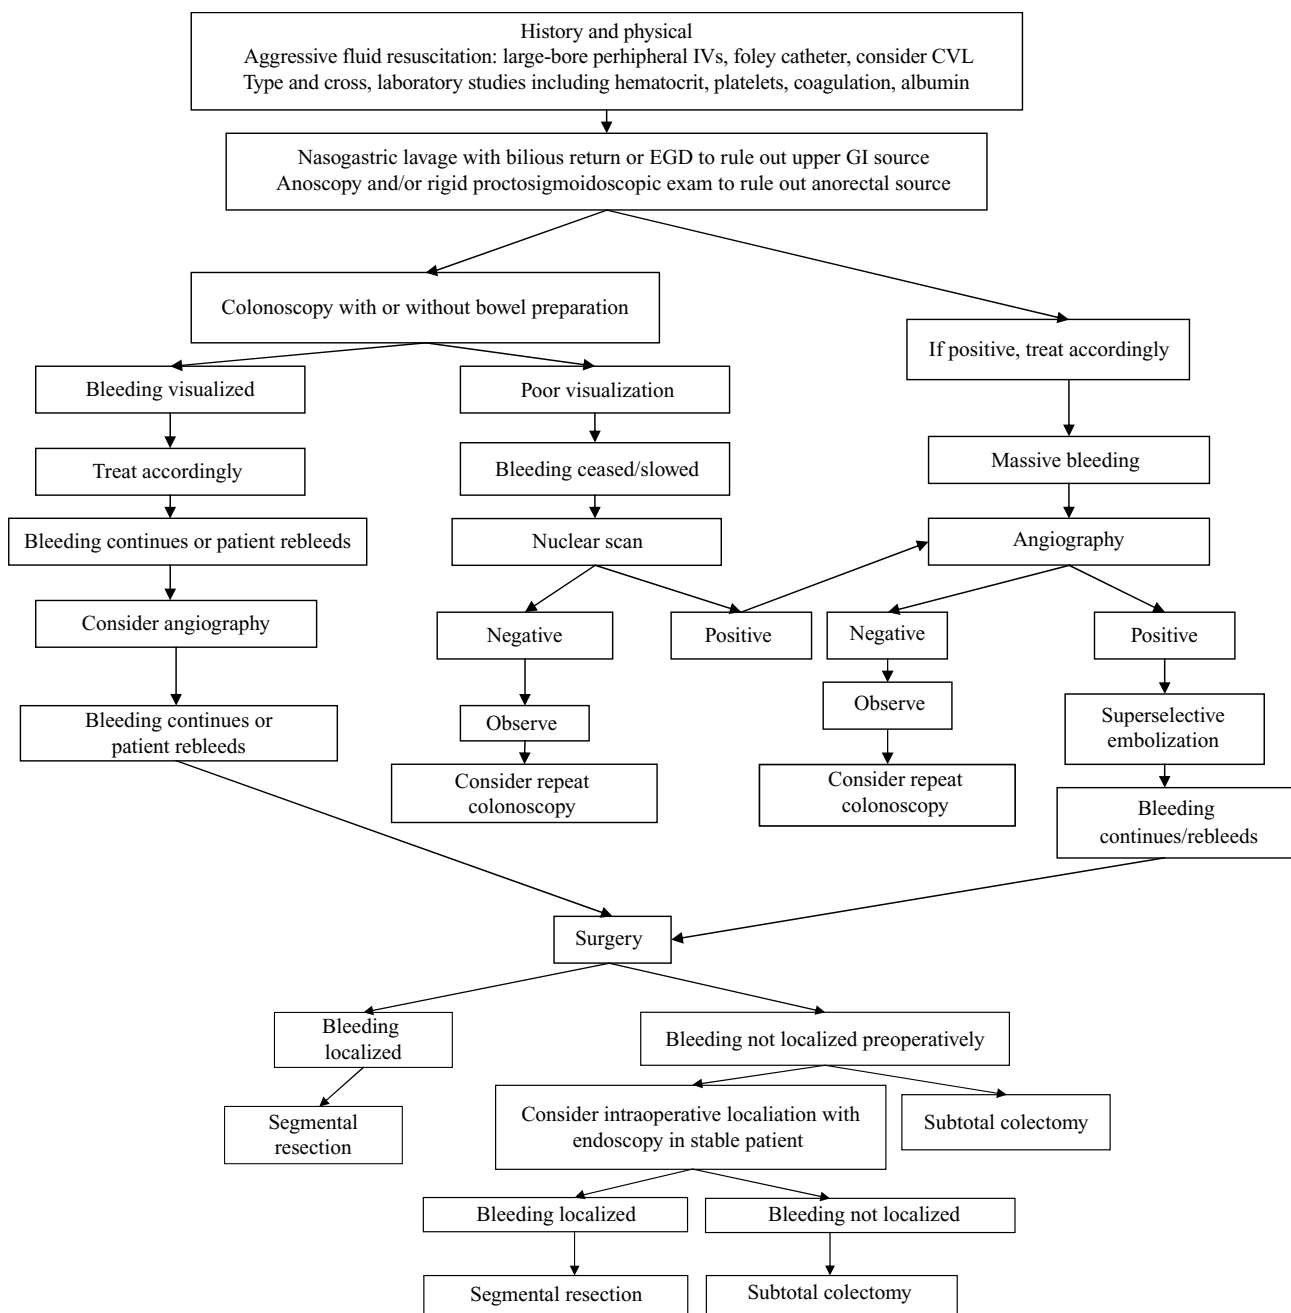

FIGURE 64.4 Management algorithm for lower gastrointestinal bleeding in the elderly patient.

Colonoscopy

Colonoscopy is a vital diagnostic and potentially therapeutic tool in the management of patients with lower gastrointestinal bleeding. It is the study of choice for patients in whom bleeding has slowed or ceased, and its role in the initial evaluation of actively bleeding patients is increasingly advocated as well. The diagnostic yield varies from 45 to

97% (see Table 64.2) [4, 5, 7, 8, 12, 14, 15, 17, 33–44]. Positive localization of bleeding by endoscopy typically depends on visualization of either active bleeding or stigmata of recent blood loss such as adherent clot, oozing, or presence of a visible vessel.

A number of studies have demonstrated that colonoscopy can be safely and successfully performed in the elderly, with morbidity rates similar to that of the general population [45–47].

Tolerance of sedation in this patient population should be given extra consideration since the elderly are more sensitive to and require less sedative compared to younger patients with similar body mass index [48]. The American Society for Gastrointestinal Endoscopy [49] guideline for endoscopic practice in the elderly recommends lower initial doses of sedatives and more gradual titration with intensified monitoring when dealing with elderly patients [50]. Careful monitoring with pulse oximetry and aspiration precautions and suctioning should be implemented.

Use of a colonic purge, usually in the form of GoLYTELY (Braintree Laboratories, Inc., Braintree, MA), has been a topic of some debate. The use of bowel preparation is fairly common and appears to be well tolerated when given as either a rapid purge (GoLYTELY given via nasogastric tube over 1 h) [8] or more slowly (GoLYTELY administered as 4 ounces every 5 min until clear) [17]. While studies have shown the safety of colon purge, even in the setting of acute bleeding [17], others argue that any prep may be unnecessary due to the cathartic effect of the blood itself. Proponents of early colonoscopy in an unprepped colon have reported accurate identification of bleeding sources in 76–97% of cases [5, 41].

The therapeutic potential of colonoscopy makes it especially appealing in the management of lower gastrointestinal bleeding, especially in elderly patients whose performance status may place them at a higher operative risk. Colonic AVMs or angiodysplasias are particularly amenable to endoscopic treatment. After a bleeding AVM is identified at colonoscopy, an attempt is made to stop the bleeding with

coagulation by heater probe, bipolar coagulation, or Nd:YAG (Neodymium:Yttrium aluminum garnet) laser therapy. Injection of vasoconstrictors such as epinephrine, may also be used. Success rates of 68–87% have been reported [36, 51, 52]. Endoscopic therapy has become first-line therapy for hemorrhage from angiodysplasia, especially in the elderly [53]. Rates of rebleeding vary and range from 13 to 53% [18, 52, 54]. Rebleeding is often amenable to repeat endoscopic treatment although surgery may be necessary in some patients. Surgical considerations will be discussed later in this chapter. Complications have been reported after endoscopic coagulation and include risk of perforation in approximately 2% of patients [55].

Endoscopic coagulation of hemorrhage from diverticulosis had not been considered feasible in the past; however, some small series have reported successful endoscopic coagulation of bleeding diverticula [37, 56]. It is now reasonable to consider colonoscopy as a plausible approach to this common cause of lower gastrointestinal hemorrhage.

Patients in whom endoscopic evaluation is not feasible may benefit from further study with a nuclear medicine bleeding scan or mesenteric angiography.

Radionuclide Scintigraphy

A nuclear medicine bleeding scan utilizes technetium-99m (99mTc)-labelled sulfur colloid or red blood cells as the imaging tracer for radionuclide scanning. Sulfur colloid marker can be prepared immediately and is rapidly cleared from the circulation; however, rapid uptake in the spleen, liver, and bone marrow can impair localization of bleeding sites. The use of tagged red cells requires some prep time, but the longer half-life of the tracer allows for repeated imaging study that may detect recurrent bleeding.

Both modalities are quite sensitive for the detection of active lower GI bleeding at rates as slow as 0.1 ml/min (see Fig. 64.5) [57]. While the sensitivity of radionuclide imaging for detecting bleeding is widely accepted, the accuracy rates at localizing bleeding are quite variable (see Table 64.3) [58–65]. There are studies that report radionuclide scanning accurately localized active bleeding in over 90% of patients who subsequently underwent surgical resection [66]. These results are not uniform, however, and other studies have shown that when used as a single localizing modality, 42% of patients had an incorrect resection when surgery was based on radionuclide scanning alone [61]. Recognizing this variable accuracy rate, most surgeons will prefer to perform a confirmatory study before proceeding with a segmental resection based on radionuclide scintigraphy alone. In fact, some advocate that the role of radionuclide scanning is to function as a screening test to

FIGURE 64.5 ^{99m}Tc -labelled RBC scan images demonstrating tracer uptake at the hepatic flexure suggestive of active bleeding.

select patients for angiography. The noninvasive, sensitive radionuclide study can select out patients with active bleeding who may benefit from the more invasive, but potentially therapeutic angiogram. This is an area of some debate. The argument in favor of utilizing screening radionuclide scanning is that it increases the yield of positive angiograms following a positive radionuclide scan. One study demonstrated an increase from 22 to 53% in angiography yield when screening radionuclide scans were used [67]. Other studies, however, failed to

demonstrate any increase in rate of positive angiograms when radionuclide scanning was used to screen patients [58, 68].

Mesenteric Angiography

Selective mesenteric angiography utilizes a percutaneous femoral artery catheter to inject radiocontrast dye to allow angiographic visualization of the celiac, superior mesenteric, and inferior mesenteric arterial systems. Active gastrointestinal bleeding is visualized as contrast extravasation into the bowel lumen (see Fig. 64.6). It is less sensitive than radionuclide scintigraphy, with an active bleeding rate of at least 1.0 ml/min required for detection [69]. Bleeding detection rates with angiography vary from 27 to 86% (see Table 64.4) [11, 66, 68, 70–74].

TABLE 64.4 Angiography for the diagnosis of lower GI bleeding

Study	Number of studies	% Bleeding sites localized

Positive studies may guide segmental resection in patients who require surgery. Angiography has the additional benefit of being a potentially therapeutic as well as diagnostic intervention. When active bleeding has been identified and the bleeding site localized, transcatheter vasopressin or embolization may be utilized to try to stop the bleeding. Vasopressin acts as a vasoconstrictor and is typically infused at a rate of 0.2–0.4 units/min. If bleeding is controlled, infusion continues for an additional 12–24 h before repeat study and catheter removal. Small series report success rates approaching 90% in controlling hemorrhage utilizing this method [75, 76]. Reported rebleeding rates are not insignificant, ranging from 18 to 57% [77–79]. Infusion of vasopressin should be approached with extreme caution, especially in the elderly population. Systemic absorption of the vasoconstrictor can potentially precipitate myocardial ischemia or peripheral ischemia. Severe coronary artery disease or peripheral vascular disease is considered a contraindication to its use. Other potential complications of vasopressin infusion include hypertension, arrhythmias, hyponatremia, mesenteric thrombosis, and bowel infarction [18].

Another angiographic modality for controlling bleeding is embolization. Historically, early use of transcatheter therapy for colonic bleeding was discouraged due to high rates of colonic infarcts. With the advent of superselective embolization therapy and subsequently lower complication rates, this technique is now widely used. When active bleeding is identified, the catheter is advanced as far distally as possible utilizing even smaller microcatheters. Superselective embolization of individual vessels may then be possible using a variety of agents (microcoils, polyvinyl alcohol particles, and gelfoam). This approach has been used with success for lower gastrointestinal bleeding from a variety of sources including the most common etiologies, namely diverticulosis, angiodysplasia, ulcers, and malignancy [78] and may be an appropriate treatment option for elderly patients with significant comorbidities and moderate to high operative risk. Reported success rates for superselective embolization of active colonic hemorrhage range from 50 to 90%, with rebleeding rates of 10–35% [76, 77, 80–83]. Approximately 20% of patients may have complications

from the procedure, including abdominal pain, intestinal ischemia or rarely, intestinal infarction. Late complications of intestinal stricture secondary to ischemia have also been reported.

Angiography may also function as a guide or bridge to surgery. In cases where bleeding has been localized but not controlled, surgery in the form of a segmental resection is indicated. Even temporary control via embolization may be beneficial. If for instance, a large AVM unamenable to complete embolization due to multiple feeding arteries is encountered, angioembolization may provide initial temporary cessation of bleeding, allowing for stabilization of the patient and optimization for definitive surgical treatment. A segmental colon resection can then be offered to the stabilized patient. In this manner, an emergency surgery situation with its inherent high morbidity and mortality is converted into a more elective and thereby safer surgical situation. Surgical intervention will be addressed in the following section.

Surgery

Indications for surgery in patients with lower gastrointestinal bleeding typically include: hemodynamic instability, persistently active bleeding, recurrent bleeding, and significant transfusion requirements typically stated as more than six units of packed red blood cells in a 24-h period [49]. With these guidelines in mind, one should also consider that because of the diminished physiologic reserve found in elderly patients and the significantly increased morbidity and mortality associated with surgery in an emergency setting, early surgical intervention is sometimes preferable. While elective surgery may be well tolerated in an elderly patient, the same procedure done in an emergency setting is accompanied by significant morbidity and mortality.

In patients meeting surgical criteria in whom bleeding is localized, a segmental resection should be done. The decision to proceed with an anastomosis versus creation of an ostomy is multifactorial and should be tailored to the individual patient. In an emergency setting and in the face of hemodynamic instability, most surgeons would not risk creation of an anastomosis and would opt for creation of a colostomy or ileostomy. Patients in whom bleeding has not been localized require a subtotal colectomy. Blind segmental colectomy in such instances is associated with rebleeding rates up to 75% and subsequent mortality rates approaching 50% [84].

The presence of associated comorbidities and need for urgent surgery are cited as independent factors associated with increased morbidity and mortality in patients with severe, acute lower gastrointestinal bleeding, regardless of age [85]. One large study of octogenarians undergoing major

intestinal surgery demonstrated that ASA (American Society of Anesthesiologists) score and emergency status were the best predictors of surgical outcome in the elderly. Those who underwent emergency surgery had a statistically significant increased mortality rate, 32% vs. 1.7% [86]. While emergency surgery for lower gastrointestinal bleeding has consistently been associated with an increased mortality, the impact may be even more pronounced in the elderly population undergoing emergency colectomy for bleeding. One retrospective study of emergency colectomy for LGIB found an increase in mortality from 21% for patients less than 70 years to 37% for patients aged 70 years and older [87]. Postoperative complications have also been found to portend a worse prognosis and high mortality rate as evidenced by the Veterans Administration National Surgical Quality Improvement Project (VA-NSQIP). In their database of elderly patients who underwent surgery, patients with more than 48 h of ventilatory assistance, acute renal failure, and systemic sepsis had mortality rates of 39%, 52%, and 45% respectively [88]. Other studies have found similar postoperative mortality rates of about 50% in patients who required postoperative ICU care [89].

Patients who undergo surgery may not be able to return home when they are ready for discharge from the hospital. Elderly patients undergoing abdominal surgery may require nursing home or rehabilitation facility placement at least 50% of the time [89]. Again, whether the surgery is done in an emergency setting is an important factor. In elderly

patients who undergo emergency surgery, discharge to skilled nursing facilities instead of home is even higher; in one series 90% compared to over 70% of patients were able to go home after surgery done in an elective setting [86].

Small Intestinal Bleeding

Bleeding from the small bowel can be a diagnostic and therapeutic challenge. Small bowel sources are classified as lower gastrointestinal bleeding since by definition they occur distal to the Ligament of Treitz. However, some advocate considering them as a separate entity given the intrinsic difficulties inherent to adequate small bowel evaluation [90]. Small bowel bleeding accounts for 2–15% of lower gastrointestinal bleeding [8] and is usually secondary to AVMs [90, 91]. Other potential small bowel sources include tumors, lymphoma, ulcers, and Crohn's disease. The length of small bowel, distance from a natural orifice, and redundancy make it difficult to evaluate thoroughly in its entirety. Most commonly used tools to evaluate the small bowel are push enteroscopy, contrast radiography, and capsule endoscopy. Capsule endoscopy is becoming the preferred modality for evaluating the small bowel for sources of bleeding. The diagnostic yield has been demonstrated to be superior to both push endoscopy (55–70% vs. 25–30%) [92, 93] and small bowel contrast radiography (31% vs. 5%) [94].

CASE STUDY

An 81-year-old female presented with bright red blood per rectum and light-headedness. Her past history was significant for hypertension and diabetes. She lived at home with her daughter but functioned quite independently, requiring no assistance with her Activities of Daily Living. On arrival in the Emergency Room, the patient was found to be hypotensive, but with a normal heart rate. On physical examination, the patient was lethargic, but arousable and able to answer questions appropriately. She appeared to be well-nourished. Her lung and heart sounds were clear. Her abdomen was soft and nontender, and the digital rectal examination was unremarkable. Immediate fluid resuscitation was started with large bore peripheral access, and a foley catheter was inserted. Her laboratory studies showed a 10-point decrease in her hematocrit compared to baseline values from routine studies one year prior. Coagulation panel was normal. Blood transfusion was initiated with

improvement in her blood pressure and urine output. Nasogastric lavage demonstrated bilious, nonbloody return, and rigid proctosigmoidoscopic evaluation showed normal-appearing internal hemorrhoids without fresh blood in the anal canal. The patient was admitted to the intensive care unit for close monitoring, continued resuscitation, and further workup. A central line was placed for central venous pressure monitoring and continued fluid resuscitation. Colonoscopy without bowel preparation was done later the same day and demonstrated pandiverticular disease and old blood, but no evidence of active bleeding. The patient remained stable with no further passage of blood per rectum. The following day the patient had passage of a large amount of blood per rectum and transient hypotension. Immediate resuscitation with IV fluid and additional blood transfusion resulted in stabilization of the patient. Urgent angiogram was obtained and demonstrated bleeding from diverticula in the area of the sigmoid colon. Superselective embolization was performed with cessation of bleeding.

(continued)

CASE STUDY (continued)

The patient was transferred back to the ICU for further stabilization, monitoring, and optimization for surgery. She had no further episodes of bleeding and developed no abdominal symptoms. She was started on a diet which she tolerated. Patient and family were counselled that given the risk of rebleeding, surgery was recommended. The benefit of elective surgical intervention compared to

the increased morbidity and mortality associated with a possible emergency scenario was emphasized to them as well. She was medically optimized and several days later underwent a mechanical bowel prep followed by an elective sigmoid resection with primary anastomosis. She tolerated the surgery well. Her subsequent postoperative course was unremarkable. She worked with the in-house physical therapists and was eventually discharged to home.

CASE STUDY: DISCUSSION

This case demonstrates several key features in the evaluation of an elderly patient who presents with lower gastrointestinal bleeding. First, while the patient is clearly volume-depleted due to her acute blood loss, she does not manifest tachycardia. This may be due to both diminished chronotropic response seen in the elderly as well as her prescribed beta blocker. Restoration of adequate preload is of paramount importance, and in this patient, was guided by both urine output and central venous monitoring. Nasogastric lavage or upper endoscopy is used to rule out an upper gastrointestinal source which can account for up to 15% of presumed lower gastrointestinal hemorrhages [32]. Early colonoscopy is being used increasingly and is well-tolerated in the elderly population. While the diagnostic yield for colonoscopy ranges from 45 to 97% [4, 5, 7, 8, 12, 14, 15, 17, 33–44], in our patient, it failed to localize the bleeding. Subsequent angiography when our patient had recurrent bleeding was able to localize and control the bleeding. Superselective embolization is being used increasingly in cases of colonic hemorrhage, and remains an attractive

treatment modality especially for patients who are at high risk for surgical intervention. In patients who are surgical candidates, embolization can also be utilized as a bridge to surgery, allowing time for adequate resuscitation and optimization, as was the case here. In light of the risk of recurrent bleeding from her diverticula, surgery was advised. It has been shown that some elderly patients can tolerate even major abdominal surgery well when done in an elective setting [86]. Emergency surgery, however, is not well tolerated, as evidenced by significant morbidity and mortality. Postoperative mortality rates for emergency colon resection in elderly patients are typically over 30% [86, 87]. Therefore, an elective segmental resection after medical optimization was offered to this patient. Avoiding the potential increased morbidity of an emergency surgery likely contributed to the ultimate disposition home for this patient. Being discharged to home would have been unlikely in the aftermath of an emergency colectomy. Most patients (up to 90%) who do survive such a scenario are ultimately discharged to a nursing home or rehabilitation facility [86]. This transition from independent living to institutional care can be distressing for some elderly patients.

Chapter 65 Ischemic Disorders of the Large and Small Bowel

Jack R. Oak and Gregorio A. Sicard

CASE STUDY

The patient is a 76-year-old male with a history of coronary artery disease who presents with an 18 month history of vague abdominal pain. The patient reports of pain after meals and approximately a 70 lbs weight loss over this time. The patient has been seen by the local gastroenterologist and has undergone both upper and lower endoscopy, which were both normal. The patient presented back to the emergency room with more complaints of abdominal pain and bloating. As part of his emergency room workup, the patient had a CT scan of the abdomen and pelvis. This revealed a tight stenosis in

the superior mesenteric artery (SMA) as well as a large 6 cm abdominal aortic aneurysm (Figs. 65.1 and 65.2). Vascular surgery was consulted. It was decided that, since the patient was a poor open surgical candidate and that the patient had suitable aortic anatomy for an aortic endograft, a staged endoluminal procedure to address both the SMA stenosis and the large abdominal aortic aneurysm was recommended.

The patient first underwent a percutaneous mesenteric angiography with successful stent placement in the SMA (Fig. 65.3). The following day after an uneventful recovery, the patient underwent successful endoluminal repair of his abdominal aortic aneurysm.

Anatomy

Intestinal ischemia is usually a disease that affects the elderly. It is useful to categorize it as acute or chronic because of the different presentations of patients and the urgency of treatment. It can also be further subdivided by etiology; causes include arterial insufficiency secondary to thrombosis or

embolus, venous thrombosis, and nonocclusive mesenteric ischemia (NOMI).

To understand the etiology of mesenteric ischemia, it is helpful to review the basic vascular anatomy of the gastrointestinal (GI) tract. The gut is supplied basically by three arteries: celiac axis (CA), SMA, and inferior mesenteric artery (IMA). The celiac axis branches almost

immediately into the common hepatic, left gastric, and splenic arteries. The celiac axis communicates with the SMA recirculation via the gastroduodenal artery and the pancreaticoduodenal arcades. The SMA originates from the aorta usually approximately 1 cm below the celiac axis. This occurs at the level of the L1 vertebra. The SMA supplies the midgut, and its major branches are the inferior pancreaticoduodenal branches, middle colic artery, right colic artery, ileal branches, and ileocolic artery. The middle colic artery comes off the proximal SMA and supplies the transverse colon. It also communicates directly with branches of the IMA. The ileocolic artery is the terminal branch of the SMA and supplies the terminal ileum, cecum, and ascending colon. The IMA is the most distal and smallest of the mesenteric arteries and is also a ventral branch of the aorta. It arises approximately 6–7 cm below the SMA, which corresponds to the level of the L3 vertebra. It supplies the hindgut, which includes the distal transverse colon, descending colon, sigmoid colon, and rectum. The left colic artery communicates with the SMA via the marginal artery.

To understand the pathophysiology of mesenteric ischemia, it is important to understand the anatomic collateral pathways. For collateral circulation between the CA and the SMA, the principle pathways are the gastroduodenal and pancreaticoduodenal arteries. Unusual anatomic variations can also provide collateral flow, such as a replaced right hepatic artery or a pancreatic or middle colic artery originating from the CA. In addition, there is an infrequent but well-recognized collateral pathway known as the arc of Buhler, which represents a direct collateral pathway between the CA and the SMA. This is thought to be due to persistence of an embryonic ventral segmental artery.

There are three major anastomotic pathways between the SMA and the IMA, the most significant of which is the marginal artery of Drummond. This artery runs within the mesentery of the colon and gives rise to the vasa recta. It receives branches from the ileocolic, right colic, middle colic, and the left colic arteries. It usually runs close to the mesenteric border of the colon. Normally, this artery is not particularly large; but with occlusion of the SMA, it can enlarge significantly. The arc of Riolan also lies within the mesentery, but is much closer to its base. This collateral connects the middle and left colic arteries (Fig. 65.4). The final potential collateral pathway between the SMA and IMA is the meandering or wandering mesenteric artery. Occasionally, this is markedly hypertrophied arc of Riolan, and other times, there is a distinct anastomotic pathway between the SMA and IMA. The IMA can be collateralized not only by the SMA, but also by the lumbar branches of the aorta, as well as from the hypogastric artery and its branches.

The venous drainage of the gut is principally via the splenic vein for the foregut, the superior mesenteric vein (SMV) for the midgut, and the inferior mesenteric vein (IMV) for the hindgut. These vessels all drain into the portal vein and hence through the liver.

Mesenteric blood vessels are highly reactive; and, accordingly, mesenteric blood flow can fluctuate between 10 and 35% of cardiac output [1]. They react to a large variety of endogenous cytokines and exogenous medications. The teleological reason given for the vasoreactivity is the widely varying metabolic needs of the gut based on the fasting and fed states. Absolute blood flow through the CA and the SMA ranges from 300 to 1,200 ml/min [2]. At rest (fasting state), the mesenteric flow is low due to high resistance with low diastolic flow with flow reversal, which is typical of high resistance beds. In the fed state, there is both systolic and continuous diastolic flow.

Although the nutritional state of the individual is often the principle determinant of blood flow, there is also extensive extrinsic and intrinsic control of splanchnic blood flow. Sympathetic tone to the gut is supplied by preganglionic cholinergic fibers of the greater splanchnic nerves [3]. These synapse in the paired celiac ganglia next to the CA. Postganglionic adrenergic fiber stimulation of the celiac axis ganglia results in vasoconstriction of the mesenteric arteries and arterioles [4, 5]. The rennin–angiotensin axis and vasopressin can both cause profound vasoconstriction. These substances are released in settings of hypovolemia [6]. The net effect of their secretion is to preserve cerebral and renal circulation at the expense of the mesenteric circulation.

Arterial Mesenteric Ischemia

Acute Mesenteric Ischemia

The most dramatic and feared form of mesenteric ischemia is *acute* mesenteric ischemia. Despite broad advances in diagnostic capabilities, surgical techniques, and perioperative management, the mortality associated with acute mesenteric ischemia is high, ranging from 60 to 90% in most series [7, 8]. The risk factors for acute mesenteric ischemia are essentially those associated with advanced age, including cardiac arrhythmias, low cardiac output states secondary to congestive heart failure, severe valvular cardiac disease or recent myocardial infarction, generalized atherosclerosis, and intra-abdominal malignancy.

Acute arterial insufficiency to the small bowel results from occlusion of the SMA. Approximately 50% of acute SMA occlusions are due to emboli [9]. Most of the emboli are cardiac in origin. They originate from left atrial or ven-

FIGURE 65.4 Collateral pathways between the SMA and IMA. The more constant marginal artery of Drummond connects the SMA and IMA via distal branches, giving of the vasa recta branches to the

bowel. The more variable arc of Riolan connects the SMA to the IMA more proximally, usually through the middle colic artery to the left colic artery.

tricular mural thrombi or from cardiac valvular lesions. They often occur in the setting of cardiac arrhythmias, particularly atrial fibrillation, or immediately following acute myocardial infarction. Although the emboli can lodge at the origin of the SMA, approximately 85% lodge more distally, usually 3–10 cm beyond the origin of the SMA where it begins to taper. The typical point of occlusion is just distal to the middle colic artery (Fig. 65.5). It is important to realize that in approximately 20% of cases, patients with SMA emboli also have emboli to other vascular beds [10]. Often intestinal ischemia caused by the embolus is exacerbated or compounded by reflexive mesenteric vasoconstriction. This compounds the ischemic insult to the bowel. Other more unusual causes include dissections of the SMA occurring in isolation or as part of extensive aortic dissection [11].

Acute mesenteric ischemia can occur up to 25% of the time in the setting of acute in situ thrombosis superimposed on preexisting atherosclerotic lesions. Although the SMA is most commonly affected, the celiac axis may be involved. Often even though these patients present acutely, on questioning they give a history consistent with chronic mesenteric ischemia (CMI), which will be discussed later in this chapter. Anatomically, these lesions occur at the origin of the SMA and not distally, as with embolic disease.

Acute mesenteric ischemia can also be nonocclusive (NOMI). The cause of NOMI is usually a low-flow state in the setting of preexisting atherosclerotic lesions, often coupled with the administration of vasoconstricting medications or digitalis. Such causes of low-flow states are most often seen in the setting of cardiac failure or sepsis. The diagnosis of

FIGURE 65.5 CT angiogram view of a patient who presented with a history of acute abdominal pain in the setting of atrial fibrillation. Patient had to be off anticoagulation due to upcoming knee surgery. (a) *White arrow*

pointing to SMA at the level right above middle colic artery as it courses behind the neck of pancreas. (b) *White arrow* showing acute occlusion in the SMA at the level of the uncinate process.

NOMI is based on a high index of clinical suspicion followed by arteriography. It requires an even higher index of suspicion than other causes of acute mesenteric ischemia because the presentation is sometimes more insidious. Mortality in the setting of NOMI is high, approaching 70%, and reflects not only the morbidity associated with mesenteric ischemia, but also probably more likely the underlying medical conditions that precipitated the episode of mesenteric ischemia [12].

The overall incidence of NOMI is decreasing despite the aging population. The likely reasons are the widespread use of systemic vasodilators in coronary care units and the improved treatment for cardiogenic shock [13]. The best chance for avoiding poor clinical outcome with NOMI resides in making the correct diagnosis and treating the underlying precipitating cause of the NOMI. It has been postulated that low flow results in peripheral hypoxemia and a paradoxical splanchnic vasospasm, which precipitates intestinal ischemia. Laboratory studies have confirmed that mesenteric vasoconstriction, intestinal hypoxia, and ischemia/reperfusion injury may play a role in the pathogenesis of NOMI. In low-flow states, the neurohormonal mediators of mesenteric vasoconstriction appear to be vasopressin and angiotensin [14]. The use of digoxin is common in patients with NOMI, and in *in vitro* and *in vivo* studies it has been shown to enhance mesenteric arterial vasoconstriction [15]. Once set in motion, mesenteric vasospasm can become persistent, even after correcting the underlying precipitating event. The persistence of prolonged vasoconstriction is responsible for the development of intestinal ischemia and subsequent infarction in NOMI [16].

Chronic Mesenteric Ischemia

Chronic mesenteric ischemia (CMI) is a relatively rare diagnosis, and there is a paucity of surgical literature involving its treatment. This being said, it appears that the number of elective operations for CMI is increasing; and given the general aging population, it is expected to continue to increase [17]. CMI is most common during late middle age. Most patients are smokers; and in contradistinction to vascular disease in other beds, most of the patients (60%) are female. In addition, there is a high incidence of other factors for vascular disease, including a high incidence of hypertension, coronary artery disease, and cerebrovascular disease [18]. It is interesting to note that, although clinically significant CMI is uncommon, asymptomatic atherosclerosis of the mesenteric circulation is common, with autopsy series showing significant stenoses in approximately 50% of celiac axes, in 30% of the superior mesenteric arteries, and in 30% of inferior mesenteric arteries [19]. The prevalence of mesenteric atherosclerotic disease increases with age, with two-thirds of patients over 80 years of age having significant stenoses.

Councilman's report was the first to recognize the syndrome of CMI with its pathognomonic symptom of postprandial pain [20]. He described three patients who presented with epigastric and midabdominal pain following eating. Typically, this pain occurs 1–2 h after a meal. The degree of pain correlates well with the quantity and the fat content of the ingested meal. Although the pain is typically described as a dull, cramping pain, there is some variability in presentation, with symptoms ranging from vague pain to severe sharp pains that can penetrate to the back. In advance cases, patients may have persistent or continuous pain, and sometimes it progresses to

acute mesenteric ischemia (in situ thrombosis of mesenteric vessels in the setting of advanced occlusive disease) [21]. Because of the postprandial pain, the patients often experience what has been termed “food fear.” Food fear results in the patient being unwilling to eat, which in turn results in the most common physical finding of CMI: weight loss. The weight loss has been described as malignant cachexia without malignancy. Frequently, these patients have been evaluated for a GI malignancy prior to making the correct diagnosis of mesenteric ischemia [22]. It is worthwhile to note, however, that a few patients present without weight loss. Presenting symptoms other than abdominal pain and weight loss that are also GI in nature, include nausea, vomiting, diarrhea, and constipation. It is thought that the symptoms may relate to the distribution of the vascular occlusive disease, with foregut ischemia (celiac distribution) leading to nausea and vomiting, midgut ischemia (SMA) leading to the common postprandial abdominal pain and subsequent weight loss, and hindgut ischemia (inferior mesenteric ischemia) leading to constipation [23].

On physical exam, the most obvious and common finding in patients with CMI is evidence of weight loss. Signs of peripheral vascular disease may also be noted as well as the presence of an abdominal bruit. Unfortunately, the diagnosis of CMI is often delayed. Given the nonspecific symptoms with which patients present, they are often evaluated for other more common diseases, such as cholecystitis, liver disease, peptic ulcer disease, and occult malignancy. These patients have undergone extensive evaluations prior to being referred to a vascular surgeon for evaluation. Due to the prolonged nature of their illnesses, nonspecific laboratory findings may include evidence of malnutrition, such as anemia, hypoalbuminemia, hypocholesterolemia, and evidence of impaired immune function. Patients have frequently undergone both plain and contrast radiologic studies of their abdomen and GI tract, but these tests are of little value. They have also often undergone both upper and lower endoscopy, which may occasionally document evidence of ischemia.

Diagnosis

Regardless the etiology of mesenteric ischemia, the key to improved patient outcome is diagnosis in a timely fashion. Unfortunately, the signs and symptoms of mesenteric arterial disease may be protean in nature, and by the time a definite diagnosis is reached, the patient may have already sustained bowel necrosis. Acute mesenteric occlusion must be considered in any patient who presents with acute onset of abdominal pain and a history of cardiac disease or recent arterial catheterization.

In regards to CMI, the most common scenario is an elderly female with a history of tobacco abuse, abdominal pain, and weight loss. Careful questioning will usually elucidate a history of postprandial pain in the periumbilical or epigastric

location. This “intestinal angina” is thought to result from inability of the stenotic or occluded visceral vessels to meet the hyperemic demands of active digestion. Patients come to associate pain with eating, and this may induce a pattern of food avoidance that results in profound malnutrition.

In NOMI, the diagnosis should be entertained when elderly patients present with the risk factors previously mentioned, including acute myocardial infarction with cardiogenic shock, congestive heart failure, arrhythmias, hypovolemic shock from sepsis, or hemorrhage or in the setting of burns and pancreatitis. In addition, the use of splanchnic vasoconstrictors including digitalis and alpha agonists are commonly seen in patients who develop NOMI. Although patients with SMA occlusion usually present with pain out of proportion to their physical findings, a significant portion of patients with NOMI (20–25%) may not have severe abdominal pain [24]. When present, the pain is often less severe or more variable in intensity, character, and location than it is in classic occlusive arterial mesenteric ischemia. Even in patients without pain, if there is unexplained abdominal distension, GI bleeding, fever, diarrhea, nausea, or vomiting, the diagnosis of NOMI should be entertained in these high-risk patients. As with other forms of mesenteric ischemia, once a patient develops abdominal tenderness or localized peritonitis, it indicates that the mesenteric ischemia has progressed to bowel infarction.

Leukocytosis and elevated serum lactate levels are nonspecific findings that may help to confirm the diagnosis of acute mesenteric ischemia. Typically, the history and physical exam reveals pain that is severe, unrelenting, and usually not well localized—usually “pain out of proportion to exam.” Progression to localized peritonitis is a late finding that suggests the presence of transmural infarction or perforation. Indeed, time is of the essence, and in those settings where detailed radiographic imaging is not readily available, a history and physical exam strongly suggestive of acute mesenteric ischemia mandates exploratory laparotomy for revascularization and assessment of bowel viability.

Imaging Modalities

Radiographic imaging plays an increasingly significant role in the diagnosis of mesenteric ischemia. Plain radiographs are commonly used to exclude other causes of the acute abdomen, such as bowel obstruction or a perforated viscus. As an early diagnostic aid in acute mesenteric ischemia, plain radiographs lack sensitivity, being reported as normal in up to 25% of cases involving acute mesenteric ischemia [25]. Unfortunately, definitive plain radiographic findings of acute mesenteric ischemia are those associated with progressive loss of tissue integrity, such as pneumatosis and portal venous air and with a much poorer prognosis at this stage.

Duplex Ultrasound

Duplex ultrasound of the mesenteric vessels is noninvasive and does not require administration of nephrotoxic contrast agents. Its utilization has primarily been in the diagnosis of CMI. As with all duplex examination, this modality is operator-dependent. An optimal patient setting, such as a thin patient with minimal bowel gas, is required to achieve quality results. Duplex ultrasonography accurately identifies high-grade stenoses of the celiac artery and SMA. In nonselected patient groups, adequate visualization may be 60%, but in more selected studies of patients thought to have CMI, the reported technical adequacy approaches 100% [26, 27].

Studies from Dartmouth and the Oregon Health Sciences University attempted to establish duplex criteria for the diagnosis of splanchnic artery stenosis and occlusion [28]. Based on repeat studies, they have determined the peak systolic velocity (PSV) and end-diastolic velocity (EDV) that correlates with a significant degree of stenosis. For the SMA, a PSV of >275 cm/s correlated with a $>70\%$ angiographic stenosis with sensitivity of 92% and specificity of 96% [29]. An EDV of >45 cm/s correlated with a $>50\%$ angiographic stenosis with sensitivity of 90% and specificity of 91% [27]. For the celiac artery, a PSV of >200 cm/s suggests a stenosis of $>70\%$ with sensitivity of 90% and specificity of 91%. Retrograde hepatic artery flow is 100% predictive of a severe celiac artery stenosis or occlusion. Celiac EDV >55 cm/s indicates a stenosis of $>50\%$ with sensitivity of 93% and specificity of 100%.

CT Angiography

Catheter angiography has long been the gold standard in delineating mesenteric arterial anatomy. However, as the availability of multidetector helical CT scans has spread, the ability to rapidly acquire high-quality CT angiographic images has made this modality the study of choice when evaluating a patient with possible mesenteric ischemia [30]. A significant amount of information can be obtained about the central arterial and venous circulation with CT angiography. Accurate timing of contrast injection and fine slices (0.5–1.5 mm) through the upper abdomen usually provides excellent visualization of the celiac artery and SMA distributions (Fig. 65.6). Other causes of abdominal pathology can also be assessed with CT. Nonspecific findings for bowel ischemia or infarction may include mesenteric stranding, bowel wall edema, or even air within the bowel wall or mesenteric vessels. The exact timing of intravenous contrast administration is tailored to the specific clinical question. Usually, a noncontrasted study is performed first to establish a baseline of the appearance of the bowel wall. The traditional use of “positive” oral contrast agents detracts from

FIGURE 65.6 CT angiogram demonstrating heavily calcific plaque at the origin of the SMA.

image quality, and most visceral computed tomography angiography (CTA) protocols recommend the use of a “negative” oral contrast agent, such as water, given before the scan. The negative contrast agent prevents image artifact from pooled areas of high opacification within the intestinal tract and actually enhances the ability to see bowel wall enhancement (or lack thereof) in the late arterial phase of the contrast bolus. Three-dimensional reconstructions may be generated from the raw CT data set, yielding a spatially oriented image that allows for the clinician to evaluate the diseased segments from different perspectives (Fig. 65.7). Some protocols may offer the use biphasic scanning, a technique borrowed from standard pancreatic and liver studies. A delayed set of images are acquired approximately 1 min after the administration of IV contrast to obtain portal venous phase imaging.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) provides excellent evaluation of the splanchnic vessels (Fig. 65.8). MRI/MRA is noninvasive and avoids the risk of allergic reaction with iodinated contrast agents. There are several caveats to the use of MRI/MRA, such as avoidance of patients with ferrous-containing implants and concern for gadolinium-induced nephrogenic systemic fibrosis (NSF) in patients with impaired renal function.

Anatomic imaging of the visceral vessels relies on contrast-enhanced MRI techniques; noncontrast three-dimensional phase-contrast MRA identifies only 66% of angiographic stenoses and creates some false-positive results [31]. The most common error of visceral MRA is overestimation of the stenosis. This weakness may result from the

FIGURE 65.7 3D reconstruction from CT angiogram of the mesenteric vessels. Lateral projection. Notice common trunk for both SMA and celiac axis. Also note heavy calcification at the common trunk.

FIGURE 65.8 MR angiogram demonstrating nonfilling of the SMA secondary to calcific plaque at the origin. *White arrow* demonstrating non-opacified SMA.

relatively poor spatial resolution of MRA. Even on the best systems, resolution is limited to 1 mm^3 . Gadolinium-enhanced MRA currently does not provide sufficient resolution to show distal emboli; nonocclusive, low-flow states; small vessel occlusion; or vasculitis [32]. Meaney and associates evaluated 14 patients with CMI; three-dimensional contrast-enhanced MRA had a sensitivity of 100% and a specificity of 87% in the overall detection of 50% or greater visceral artery stenosis [33]. The lack of specificity was due to false-positive diagnosis of IMA stenoses. Looking only at the subset of celiac artery and SMA data, the sensitivity and specificity were 100% for the detection of 50% or greater stenosis. In a

similar, more recent study by Carlos et al., two blinded observers reviewed gadolinium-enhanced MRA studies and compared them with conventional angiography in 26 patients suspected to have CMI. The overall accuracies for the detection of 50% or greater stenosis or occlusion in the celiac artery, SMA, or IMA were 95 and 97%.

Secondary signs of mesenteric ischemia, such as fat or bowel wall thickening, which are routinely delineated by CT, are more difficult to assess with MRI. In general, the anatomic evaluation of the mesenteric arteries is limited to the proximal celiac artery and SMA only, and the evaluation of SMA branches or IMA is limited by the spatial resolution of MRI techniques. MRA is not routinely the first imaging study to obtain in the setting of AMI because of time delay. The utility of MRA in CMI depends on the quality of the instrumentation, the sophistication of the software, and the skill of the interpreting radiologist, especially when other modalities are available.

Catheter-Based Arteriography

Finally, catheter-based arteriography is a time-tested modality offers superbly detailed images of the visceral arterial tree, and venous patency may also be assessed on delayed images. Due to the time urgency in the treatment of AMI, as well as the burgeoning availability of CTA, the use of catheter angiography prior to laparotomy is now distinctly uncommon. In the setting of CMI, diagnostic angiography may be combined with therapeutic intervention in selected candidates (Fig. 65.9). To document stenoses of the origins of the SMA and celiac axes, lateral views are best. Usually, involvement of at least two mesenteric vessels is required to diagnose symptomatic CMI. It is unusual for a patient to be symptomatic from occlusion of only one vessel. Additional evidence of chronic ischemia is evidenced by hypertrophy of collateral pathways, including the marginal artery of Drummond and the arc of Rioloan (Fig. 65.10). Relative drawbacks of this technique include the need for arterial instrumentation and administration of nephrotoxic contrast agents.

Treatment

Once the diagnosis of mesenteric ischemia is made, prompt surgical intervention is necessary. However, the approach for acute mesenteric thrombosis from an embolus is entirely different from that of thrombosis.

Unfortunately in the acute setting, the patient has usually presented with advanced stages of ischemia and thus emergent exploration is warranted. The abdomen is explored through a generous midline incision, typically extending from xiphoid to pubic symphysis. The main goal of the

FIGURE 65.9 Lateral projection of SMA during catheter arteriography. Note wire crossing lesion in preparation for deployment of a stent.

FIGURE 65.10 Lateral view of SMA angiogram. Note large collateral between celiac axis and SMA as demonstrated by *black arrow*.

explorations is to (1) determine and confirm the cause of the extent of the mesenteric disease and (2) assess the viability of the bowel. The extent and pattern of bowel ischemia can offer valuable clues concerning the cause of bowel ischemia, thereby aiding in planning for revascularization.

The bowel assessment for viability is made by visual inspection, with an attempt to differentiate between ischemic

but potentially viable bowel and infarcted bowel. Obvious signs of bowel necrosis include bowel wall that is an ashen, dull gray color, lacking the normal glistening sheen, and bowel that does not exhibit peristalsis. Other adjunctive measures include trying to obtain Doppler signals along the antimesenteric side of the bowel wall, intravenous administration of fluorescein, and using a Wood's lamp to see the extent of bowel perfusion. Unfortunately, some patients have such obvious, extensive bowel infarction that after resection they would be left with insufficient bowel to sustain life. In such cases, it is appropriate to close without attempting to restore blood flow or resect the infarcted bowel.

Bowel that appears severely ischemic may be viable after revascularization. Thus, in all but the case of obvious bowel necrosis, the surgeon should proceed with revascularization before resecting any intestine. The questionable bowel should be kept moist in well covered with warmed saline solution during the remainder of the case. At any time after revascularization that there is any questionable appearing bowel, it is always safe to plan for a “second-look” laparotomy after 24–48 h to see if more bowels can be either saved or sacrificed during this second exploration.

Exposure of the SMA for embolectomy is achieved by retraction of the transverse colon cephalad and the small bowel and its mesentery inferiorly. One can trace the middle colic artery down to its junction to the SMA as a means to identify the SMA. An incision is made in the small bowel mesentery near the root of the mesentery, directly over the area where the superior mesenteric vessels lie. A segment of the proximal SMA and its branches (jejunal branches and the middle colic artery) are controlled. The artery is opened transversely if direct repair after embolectomy is planned, or longitudinally if the vessel is diseased and may need to be closed with a potentially saphenous vein patch. Proximal embolectomy is performed with a 3 or 4 French (F) embolectomy balloon catheter. With extraction of the embolus, pulsatile inflow should be expected. Distal embolectomy is performed with a smaller catheter, typically 2 or 3 French embolectomy catheter. Difficulty in passing a catheter down multiple branches of small size adds to the complexity of performing the distal embolectomy (Fig. 65.11). An alternative or adjunct to balloon embolectomy of the distal mesenteric vessels is for the surgeon to place a hand on either side of the mesentery and “milk” thrombotic material out of the vessels. When all thrombus is removed, the arteriotomy is closed primarily or with vein patch, and flow is reestablished.

In regards to CMI, it is indicated to offer revascularization whenever a patient is symptomatic. The ultimate goal is to restore a normal mesenteric circulation, thereby allowing normalization of the nutritional status and alleviation of abdominal pain. Three basic techniques are available for revascularization: bypass grafting, transaortic endarterectomy, and more recently, angioplasty with possible stenting.

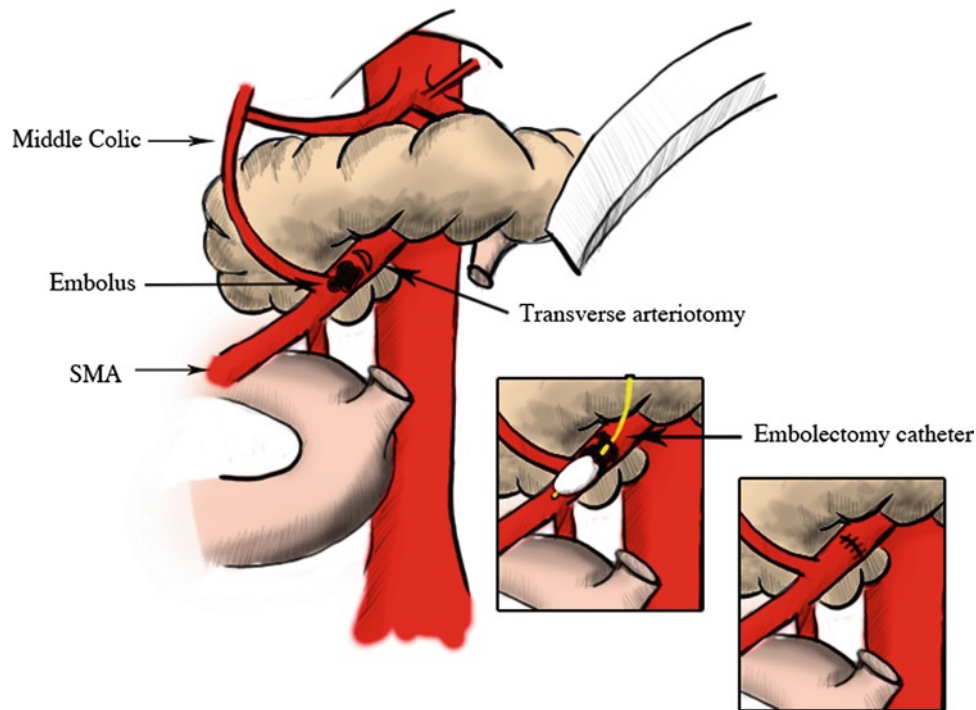

FIGURE 65.11 Embolectomy for acute mesenteric ischemia. Embolus typically lodged at the takeoff of middle colic from SMA. A small transverse arteriotomy is made with an 11-blade. Passing a 2 or 3 French

embolectomy catheter distally to remove lodged embolus and a 3 or 4 French catheter proximally will usually restore pulsatile inflow. The arteriotomy is then closed with nonabsorbable monofilament suture.

The choice of therapy must be individualized not only to the patient's anatomic lesions, but also to the patient's comorbidities. The ideal procedure for CMI remains a subject of debate [34]. Preoperative evaluation of patients for mesenteric revascularization is not different from preparing for any other major vascular reconstruction. As indicated by the patient's general medical condition, he or she should be evaluated for coronary artery disease, cerebrovascular disease, or renal vascular disease.

It is also important to realize that these patients are often nutritionally debilitated and as a result are both volume-contracted and anemic. These conditions should be approached in an urgent, aggressive manner prior to surgery. Because of the high incidence of multisystem disease, invasive intraoperative monitoring with radial artery and pulmonary artery catheters is recommended. As part of this goal, it is hoped that the progression of mesenteric ischemia to visceral infarction is avoided as well. In unusual circumstances, prophylactic mesenteric revascularization is undertaken in patients undergoing major aortic reconstruction who have had incidentally identified significant mesenteric artery stenoses [35]. The rationale for doing this is that the patient may be at increased risk for perioperative visceral infarction due to unexpected hypovolemia, hypotension, or disruption of the collateral circulation by the periaortic dissection. In the absence of performing aortic procedures, prophylactic mesenteric revascularization is not usually

recommended. As previously noted, mesenteric artery occlusive disease is widely present in autopsy series, but most of it was asymptomatic.

Mesenteric Bypass

Several techniques are available for performing mesenteric bypasses. Because mesenteric ischemia usually results from multiple-vessel disease, multiple-vessel reconstruction is usually recommended. Bypasses are generally categorized into two broad techniques: antegrade and retrograde. Antegrade bypass grafts generally originate from the supraceliac aorta, which is an excellent site for originating a bypass graft because it is usually spared significant atherosclerotic or aneurysmal disease. Autologous material or synthetic grafts can be used without any documented difference in efficacy. Polytetrafluoroethylene (PTFE) and Dacron grafts have been used. If there is any question about contamination at the time of surgery (e.g., if bowel resection is necessary), an autologous conduit, usually the saphenous vein, should be used.

The supraceliac aorta is usually exposed transabdominally, which can be done through either a midline incision or bilateral subcostal incisions. After thorough exploration of the abdomen, the supraceliac aorta is exposed by first mobilizing the lateral segment of the left lobe of the liver, which is retracted inferiorly and to the right. The gastrohepatic

omentum is divided and the lesser sac entered. Care is taken not to injure the esophagus, which is easily identified by palpating the nasogastric tube within its lumen. The right crus of the diaphragm is divided with electrocautery. In this fashion, approximately 7–110 cm of distal thoracic and proximal abdominal supraceliac aorta can be isolated. The celiac axis and SMA are skeletonized. The rationale for doing multivessel revascularization is to maximize symptomatic relief and prevent symptomatic recurrence and visceral infarction, which may result from single-graft failure [36]. Supraceliac aortic control is obtained with a partially occluding clamp if possible. This step helps limit the large increase of afterload on the heart that can result from supraceliac cross-clamping, as well as renal and visceral ischemia. If a synthetic graft is used, a bifurcated graft of appropriate size is chosen. The proximal anastomosis is sewn in an end-to-side fashion to the aorta. One limb is then sewn in end-to-end to the celiac axis. In a similar fashion, an end-to-end anastomosis is performed to the SMA. Sometimes it is necessary to completely cross-clamp the supraceliac aorta, but the proximal anastomosis can usually be completed in 20 min or less, and this amount of visceral and renal ischemia time is well tolerated. A straight graft to the SMA is placed with reimplantation of the celiac axis onto that graft. In addition, as mentioned, the SMA anastomosis can usually be performed to the proximal SMA anterior to the pancreas. If necessary, due to extensive disease within the proximal SMA, the graft can be tunneled behind the pancreas with construction of the distal anastomosis to the SMA distal to the point where the SMA has passed through the uncinate process of the pancreas.

An alternative technique uses an autologous conduit. This is done in the setting of the contaminated or clean-contaminated case secondary to the need for bowel resection. One effective and simple technique is to perform an inline bypass using saphenous vein to the SMA, with the hood of the vein graft forming a patch angioplasty at the origin of the celiac axis. In this fashion, both the celiac axis and the SMA are revascularized. Once revascularization is completed, blood flow is restored to the viscera. This is done in coordination with the anesthesia team to avoid declamping hypotension. Following this step, the bowel is carefully inspected to ensure that adequate flow has been restored.

Occasionally, the supraceliac aorta is not suitable as the origin for the antegrade bypass because of aneurysmal or atherosclerotic disease or secondary to previous surgery at the diaphragmatic hiatus. Also, some patients cannot tolerate supraceliac cross-clamping. In this situation, retrograde bypass from either the infrarenal aorta or the iliac vessels can be performed. The infrarenal aorta is also often used as the inflow source if mesenteric revascularization is being performed at the time of concomitant infrarenal aortic reconstruction. The synthetic aortic prosthesis provides an excellent inflow vessel. Standard transperitoneal exposure of the iliac vessels or of the

infrarenal aorta is performed. It is necessary to mobilize the ligament of Treitz fully, and then the proximal SMA is isolated below the inferior border of the pancreas at the base of the small bowel mesentery. Once again, the choice of conduit can be saphenous vein or prosthetic graft. The proximal anastomosis is performed to either the distal infrarenal aorta or the proximal common iliac artery in an end-to-side fashion. The conduit is left with a long, gentle curve around the base of the mesocolon, which not only facilitates the anastomosis to the SMA, but also helps avoid kinking, which tends to occur with short grafts, particularly saphenous vein grafts [37]. The anastomosis to the SMA can be performed in an end-to-end or end-to-side fashion. In the event that the celiac axis is to be revascularized at the same time, a bifurcated graft can be used, or a “piggyback” graft can be sewn onto the SMA graft. The celiac axis is exposed as previously described. Once again the graft is tunneled to a retropancreatic tunnel and can be anastomosed to the celiac axis or the common hepatic artery.

These operations, as might be expected, are associated with significant perioperative mortality, which averages approximately 6% for patients undergoing revascularization for CMI [38]. These patients, despite their significant comorbidities, have an approximately 75–80% 3-year survival following surgery. Graft thrombosis with visceral infarction is a significant cause of both early and late mortality [39]. The rate of symptomatic graft failure has been documented to be 15% at an average follow-up of 38 months. Another more recent series by McMillan et al. has shown that an objective primary patency rate of 89% at 72 months was obtained in a single series. In that series, there was no difference between primary patency rates in patients undergoing retrograde or antegrade bypass. There were also no differences noted for the type of conduit used. Overall, given the extensive comorbidities of these patients and their underlying atherosclerotic disease, visceral revascularization is a durable procedure, and the morbidity and mortality of the procedure are acceptable.

Transaortic Mesenteric Endarterectomy

For occlusive disease limited to the origins of the visceral vessels, transaortic mesenteric endarterectomy is a well-described technique for mesenteric revascularization. The advantages of endarterectomy are that (1) it eliminates the occlusive lesion; (2) it is an anatomic revascularization and is therefore not subject to turbulent flow or problems with graft compression or alignment; and (3) it provides an autogenous method for multiple-vessel reconstruction [40]. The patients are prepped for surgery in a similar manner with all the precautions mentioned earlier. The visceral abdominal aorta can be exposed through a thoracoabdominal incision or a midline or extended left subcostal incision using medial visceral rotation. The advantage of medial visceral rotation is that it avoids

entering the thoracic cavity. Exposure of the upper abdominal aorta is accomplished via left-sided medial visceral rotation. First, the splenic flexure of the colon is mobilized by dividing its peritoneal attachments, and then the descending colon is mobilized along its lateral peritoneal reflection. In a similar fashion, the spleen is mobilized by dividing its lateral peritoneal attachments, and it is rotated medially. The dissection plane is established in the retroperitoneum and lies between Gerota's fascia and the peritoneal envelope and posterior to the tail of the pancreas. Once the spleen and pancreas are mobilized medially, the left renal vein is identified and is dissected free from the renal hilum to the vena cava. Division of the adrenal and lumbar branches of the renal vein allows the vein to be retracted inferiorly, thereby providing optimal exposure of the perirenal aorta. The left crus of the diaphragm is divided along the left anterior lateral aorta. Once it is divided, the distal thoracic aorta is exposed, which is the site of proximal aortic control. The side of distal control depends on the extent of the planned endarterectomy. Usually, infrarenal aortic control is necessary because of the proximity of the SMA to the renal arteries. The origins of all the visceral vessels are circumferentially dissected free. When circumferentially dissecting the vessels, care is taken to palpate the vessels to make sure the dissection proceeds beyond the margins of the disease. If the disease goes well beyond the ostium, aortic endarterectomy is not possible.

Once vascular isolation is obtained, an aortotomy is performed. The extent of the aortotomy depends on whether endarterectomy of the renal vessels is planned. A standard endarterectomy is performed around the base of each vessel. Usually with ostial disease, gentle eversion endarterectomy suffices and good endpoints are obtained. Once the endarterectomy is completed, the aortotomy is closed. On occasion, it is not possible to complete the SMA endarterectomy through the transaortic incision. In this case, an arteriotomy can be made on the SMA, and a good endpoint can be obtained. If the more distal SMA is diseased, and it is thought that endarterectomy cannot suffice, a longitudinal arteriotomy can be performed and then closed with a patch angioplasty using saphenous vein.

This operation has proved to be durable. Its drawback is that the patient must be able to tolerate an extensive abdominal dissection as well as a supraceliac aorta cross-clamp. In addition, there is the anatomic constraint that the occlusive disease must be limited to the ostium.

Percutaneous Options

The final option for mesenteric revascularization is percutaneous transluminal mesenteric angioplasty. The application of angioplasty techniques to mesenteric ischemia is in its infancy. Currently, there are no standard guidelines for the

application of angioplasty, and the literature suggest that it is being reserved for patients considered to be "extremely poor surgical candidates," which historically have included the elderly [41]. However, most of the reports, coming from small, single-center experiences, do seem to implicate that the percutaneous approach may offer advantages in the short term, such as shorter hospital stay and less perioperative complications than the open surgical approach [42]. The benefits from the percutaneous approach, however, come at the cost of lower primary patency rates and higher reintervention rates [43]. For such reasons, percutaneous options may be ideal for the high-risk elderly patient – where long-term durability is not the main concern; but rather achieving symptomatic relief to help improve the nutritional status of the patient at minimal morbidity to the patient [44]. The improving technology for angioplasty, including better catheters, guidewires, low-profile balloons, and stent technology, have made angioplasty more applicable to increasingly complex lesions. Ideal lesions for angioplasty are short-segment ones that are not being caused by extrinsic constriction. It goes without saying that any patient who presents with acute mesenteric ischemia and evidence of intestinal infarction requires immediate laparotomy, not angioplasty. The technique for angioplasty of a mesenteric vessel is similar to that of any other lesion. Unlike most other peripheral vascular interventions that are accessed via a femoral approach, a left brachial approach may be easier given the acute angle of the SMA takeoff from the aorta. The lesion must be able to be crossed with a guidewire. Following placement of the guidewire, a balloon must be passed over the wire across the lesion. In addition, if necessary, a stent may be placed.

Moreover, using a percutaneous approach can be a useful adjunct when treating patients with NOMI. Once the diagnosis of NOMI is made, intra-arterial papaverine infusion into the SMA is possible. The usual dose is in the range of 30–60 mg/h. The patient's response to vasodilator therapy is monitored by clinical and angiographic criteria. Of importance is that there is a resolution of abdominal pain. Arteriography should be repeated to document that the vasospasm has been broken. Once the vasospasm is broken, papaverine treatment should continue for another 24 h. It is important to carefully monitor the patients receiving intra-arterial vasodilator therapy, as marked hypotension can result. These patients obviously must be cared for in the intensive care unit.

Mesenteric Venous Thrombosis

Mesenteric venous thrombosis is the least common form of mesenteric ischemia. It currently accounts for only 5–15% of all cases of mesenteric ischemia [45]. As with arterial ischemia,

mesenteric venous thrombosis can be divided into acute and chronic presentations. Acute mesenteric venous thrombosis is a process in which the patient presents with <4 weeks of symptoms. Patients who present with more than 4 weeks of symptoms without evidence of bowel infarction, or those who have a diagnosis of mesenteric venous thrombosis made incidentally and it is clinically insignificant, are classified as having chronic mesenteric venous thrombosis [46].

The etiology of mesenteric venous thrombosis is classified into one of two categories: primary or secondary. Primary mesenteric venous thrombosis is a spontaneous, idiopathic event with thrombosis of the mesenteric veins that is not associated with any other disease process or a hypercoagulable state [47]. The frequency of this diagnosis has decreased with the improved ability to diagnose hypercoagulable states. The conditions associated with secondary mesenteric venous thrombosis are hypercoagulability, malignancy, cirrhosis, splenomegaly, intra-abdominal infection, trauma, and pancreatitis. The hypercoagulable states are usually related to hematologic disorders and include protein C and S deficiency, antithrombin III deficiency, dysfibrinogenemia, abnormal plasminogen, polycythemia vera, thrombocytosis, sickle cell disease, and factor V Leiden mutation.

Although patients with acute mesenteric venous thrombosis can present with a picture similar to that of acute arterial thrombosis, their presentation is usually not as dramatic and the symptoms not as severe. Therefore, there is often a delay in diagnosis. This delay is a major contributory factor to the relatively high mortality reported in the literature secondary to mesenteric venous thrombosis [48]. Patients usually present with a several-day to several-week history of diffuse, nonspecific, and often intermittent abdominal pain. Typically, these symptoms are gradually progressive. Aside from abdominal pain, other symptoms occur much less frequently. Physical findings are often vague, with abdominal distension being the most common, but it is seen in only approximately 50% of patients. Peritonitis is present only in advanced cases that have progressed to bowel infarction. Studies have indicated that along with bowel infarction requiring resection, advanced age, underlying malignancy, and prolong duration of symptoms (more than 5 days) are usually predictive of a poor outcome [49].

As with NOMI, laboratory tests are usually not helpful for diagnosing acute mesenteric venous ischemia. Leukocytosis is seen in some patients, as are elevated amylase and LDH levels; but once again, this is in the setting of mesenteric infarction.

Diagnosis

Mesenteric venous thrombosis is diagnosed by radiographic means. Plain abdominal films are usually nonspecific and help

FIGURE 65.12 CT angiogram, delayed venous phase. *White arrow* is pointing to thrombus within the superior mesenteric vein.

little with the diagnosis. The most common finding is a nonspecific ileus. Computed tomography (CT) scanning has proved to be the most sensitive diagnostic test for mesenteric venous thrombosis. CT scanning accurately identified thrombus within the SMV and the portal vein [50] (Fig. 65.12). Magnetic resonance imaging has also proved to be sensitive [51]. Duplex scanning of the mesenteric veins can be performed as well, but has a slightly lower sensitivity than CT scanning.

Unlike with other forms of mesenteric ischemia, mesenteric arteriography has proved not to be diagnostically sensitive. Evidence of venous thrombosis can only be seen on the venous phase of a selective SMA injection. As with other forms of mesenteric ischemia, any patient who presents with evidence of peritonitis or other signs of bowel infarction should undergo emergent exploratory laparotomy. If mesenteric venous thrombosis is diagnosed prior to surgery, anticoagulation with intravenous heparin should be started immediately. If it is diagnosed at the time of laparotomy, heparin should be initiated immediately.

Treatment

The guidelines for bowel resection are the same as with any other form of mesenteric ischemia. Frankly necrotic segments are removed. If there are questionable areas, a second-look laparotomy is performed. In general, venous thrombectomy is not recommended, as it is almost uniformly unsuccessful; although it may be indicated in a few selective circumstances, such as when it can be clearly documented that there is thrombus within the SMV within 1–3 days of the initial symptoms [52]. More recently, thrombolytic therapy has been used, but its efficacy is unclear, and its use remains controversial [53]. In patients who do not present with peritonitis or who have

evidence of bowel necrosis, optimal management consists of anticoagulation and observation. Anticoagulation with intravenous heparin acutely is followed by chronic anticoagulation with warfarin. Chronic anticoagulation is associated with improved survival compared with the survival of those who did not undergo anticoagulation [25]. The underlying cause of the mesenteric venous thrombosis does not appear to affect survival. It is recommended that this regimen continue for the life of the patient [54].

Chronic mesenteric venous thrombosis is different from acute mesenteric venous thrombosis. Patients usually present with vague abdominal pain or slight distension. The most frequent presentation is asymptomatic, with the thrombosis being an incidental finding on diagnostic imaging for another complaint. No specific therapy is generally indicated.

Ischemic Colitis

The final category of mesenteric ischemia in the elderly to be considered here is ischemic colitis. As with other causes of mesenteric ischemia, ischemic colitis can be caused by occlusive or nonocclusive lesions. The colon is normally supplied on the right side by the SMA and on the left by the IMA and branches of the hypogastric arteries. The collateral pathways that exist among the SMA, the IMA, and the hypogastric arteries were described earlier in this chapter. Ischemic colitis results when there is obviously decreased flow in one of these vascular beds. Patients susceptible to this problem are those who have absent or poorly developed collateral pathways. It is important to know that previous colonic surgery can interfere with these pathways. The splenic flexure of the colon is in a watershed area between the IMA and SMA. It is more susceptible than the rest of the colon to ischemic injury. In 5% of the population, the marginal artery of Drummond is absent or diminutive, and it is also poorly developed in the right colon of nearly 50% of the population. This helps explain the relatively frequent occurrence of right-sided ischemic colitis [55]. Ischemic colitis results when the colon is rendered ischemic for any of the reasons presented previously.

Ischemic colitis tends to produce local and systemic symptoms. In particular, there is a release of inflammatory cytokines and other mediators of inflammation, which is thought to be secondary to endotoxemia and portal bacteremia. These situations result from the increased mucosal permeability caused by ischemia [56]. Also, if there is reperfusion of the ischemic areas, there can be release of oxygen-free radicals and other toxins, resulting in further systemic symptoms. Moreover, recent studies suggest that neutrophils activated during the ischemia/reperfusion process play an important role [57]. It is therefore not surprising that patients

with ischemic colitis can be extremely ill and that their mortality is often secondary to multisystem organ failure.

Diagnosis

The typical patient who presents with ischemic colitis is an elderly man with comorbid conditions, including cardiac disease, peripheral vascular disease, diabetes mellitus, or renal insufficiency. The presentation of ischemic colitis can be insidious, with patients complaining of abdominal pain, distension, and diarrhea. Progression to lower GI hemorrhage occurs at an advanced stage of ischemic injury. It usually results from sloughing of the mucosa.

Three degrees of severity of ischemic colitis have been described [58]. The mildest form involves only the colonic mucosa and submucosa. It is estimated that more than half of all patients with ischemic colitis have experienced this degree of the disease. These patients typically have abdominal pain and bloody diarrhea, but the symptoms typically resolve with conservative measures and surgery is not required [59]. The most severe form of ischemic colitis, which only affects 10–20% of patients, involves full thickness necrosis of the colon, requiring immediate surgical resection. The intermediate of ischemic colitis involves the mucosa, submucosa, and the muscularis layer of the colon. It can lead to chronic stricture due to scarring when the lesion heals or to persistent symptoms. Often, in patients with the two milder forms of ischemic colitis, the initial presenting symptoms are vague and nonspecific. Once again, as with other forms of mesenteric ischemia, a high index of suspicion should be maintained in patients who present with GI symptoms.

As with other forms of mesenteric ischemia, blood tests, although providing collaborative evidence of colonic ischemia, are nonspecific. As with midgut ischemia, the presence of metabolic acidosis and elevated CPK and LDH levels are indicative of advanced colonic ischemia. The most definitive way to diagnose ischemic colitis is by endoscopic evaluation. Acutely, pale mucosa with areas of petechial hemorrhage is seen with mild ischemia; more severe degrees of ischemia are indicated by a dark (blue to black) mucosa, which may be accompanied by mucosal sloughing and ulceration [60]. Because the findings at the time of endoscopy can be confused with other forms of colitis, biopsy and histological examination may prove to be useful. With ischemic colitis, there is destruction of the crypts, sloughing of the epithelium, edema, thrombosis of the capillaries, and a relative lack of inflammatory cells. Later findings include stricture and fibrosis; biopsy reveals extensive transmural fibrosis with mucosal atrophy [61].

Unlike other forms of mesenteric ischemia due to arterial lesions, angiography is usually not helpful in this setting. This is because often the lesion leading to ischemic colitis is

more peripheral and therefore more difficult to detect [62]. CT scans are often obtained due to the unclear diagnosis in the patient presenting with abdominal pain; they are often normal in these patients, particularly those who present early in the course of their illness [63]. A late finding highly suggestive of ischemic colitis is pneumatosis [65]. The most frequent positive finding is circumferential thickening of the colonic wall, which is secondary to edema or hemorrhage, but it is nonspecific [65]. The use of other imaging studies remains to be experimental, and so far they have proved to be insensitive [66, 67] as with other forms of ischemia; findings on plain films are not often seen, are usually nonspecific, and when seen, usually are due to advanced ischemia. Contrast studies are infrequently used to evaluate patients with acute abdominal pain; if obtained, thumb printing due to submucosal edema and hemorrhage is the classic finding of ischemic colitis.

Treatment

The management of patients with ischemic colitis is individualized and depends on the patient's presentation. Most patients who present with ischemic colitis do not have an acute abdomen, and therefore emergent surgery is usually not necessary. These patients are managed with intravenous fluids, administration of broad-spectrum antibiotics, and stopping oral intake. The precipitating events for ischemic colitis, which are often low-flow states, should be corrected. Within 1 week, most patients with mild form of ischemic colitis respond well to treatment [68]. In the patient who presents with ischemic colitis with no clear cause, visceral angiography can be considered; but once again it has a relatively low yield.

Any patient who presents with an acute abdomen requires emergent surgery. Those who fail to respond to conservative measures and who have persistent bleeding or low-grade sepsis require surgical intervention. Surgical treatment involves resecting the ischemic segments of colon. It is recommended that patients have a colostomy or an ileostomy, with a subsequent procedure to restore intestinal continuity [69]. Patients with ischemic colitis have a relatively high mortality, but it is usually due to the underlying condition that precipitated the ischemic colitis. In this sense, it is similar to NOMI. Obviously, patients who require surgery have an even higher mortality rate [70]. Elective aortic reconstruction for aneurysm disease is associated with a 1–2% incidence of ischemic colitis [71]. In the emergent setting of a ruptured abdominal aortic aneurysm, the incidence of ischemic colitis has been reported to be as high as 60% [72]. This association with ischemic colitis and aortic reconstruction has often been centered around the IMA. Replanting the IMA in aortic

surgery to prevent ischemic colitis has been discussed, and few randomized trials have been done to compare the incidence of ischemic colitis in patients with and without IMA revascularization. One recent prospective study, however, found that there was no significant reduction in postoperative ischemic colitis in patients with IMA revascularization, however, found that age and intraoperative blood loss correlated with an increased risk of developing ischemic colitis [73]. Ischemic colitis following aortic surgery is associated with a high mortality rate, which has been reported to be in excess of 50% [74]. In the subgroup of patients who require emergent colectomy, mortality is nearly 90%. As with other forms of mesenteric ischemia, the key to a successful clinical outcome is a timely diagnosis, which requires a high index of clinical suspicion. Therefore, in any patient who has undergone aortic reconstruction and develops bloody or heme-positive diarrhea, has an unexplained high fluid resuscitation requirement, presents with fever and leukocytosis of unknown origin, or has an unexplained acidosis, the diagnosis of colitis should be suspected and evaluation including endoscopy should be undertaken.

Chapter 66

Surgery for Inflammatory Bowel Disease in the Elderly

Stefan D. Holubar and Bruce G. Wolff

Early in the twenty-first century, inflammatory bowel diseases (IBD) remain idiopathic chronic conditions and are often considered afflictions of the young. However, significant and growing proportions of those either presenting with or requiring surgery for Crohn's disease (CD) or chronic ulcerative colitis (CUC) are elderly. Currently, it is estimated that >1.1 million persons in the United States suffer from IBD [1], of which an estimated 13–16% are over the age of 60 years. In addition, an estimated 65% of all CD patients and 25% of all CUC patients require surgery within 10 years of diagnosis [2]. Thus, as the proportion of the American population over age 60 increases, surgeons and other health-care providers who care for IBD patients can expect to see a relative increase in elderly patients with IBD who require surgical intervention [3].

Understanding the differences in disease presentation, indications for surgery, and physiologic differences in the elderly as compared to the young patients with IBD is an important consideration to deliver the highest quality care possible in timely manner, thus optimizing the risk of morbidity in this at-risk population [4]. In addition, minimally invasive operative approaches, which are increasingly being applied to patients with IBD, must be tailored to the needs of the elderly patient. In this chapter, we review the epidemiology of IBD (including the natural history and presentation), differential diagnosis, indications for surgery, and operative principles (including minimally invasive [laparoscopic] techniques), which are relevant to elderly patients with IBD. A summary of the highlights of this chapter is provided in Table 66.1.

Epidemiology

Several factors influence the interpretation of data regarding the incidence of inflammatory bowel disease (IBD) in the elderly: the source of the data (population-based studies

versus clinical series), the geographic setting (incidence rates vary between countries [5]), the definition of elderly, the historic age of the series, and the disease definition [3]. More accurate data on the incidence of IBD in the elderly are derived from population-based studies because clinical series are typically retrospective descriptions of patients from a single institution, often a tertiary center where complicated cases may be overrepresented. Late-onset cases are variably defined in patients ranging from >40 years to those >65 years of age.

Crohn's Disease Incidence

Crohn's disease (CD) has been called a disease of the twentieth century, having first been described by Crohn and his colleagues in 1932 at Mount Sinai Hospital, New York [6]. The incidence of the disease ranges from 3.1 to 14.6 per 100,000 person-years [7] and usually accounts for one-third to one-half of cases of IBD. Multiple studies have indicated that the incidence of CD in Western society is increasing, and North America is considered a high-incidence area [7]. Interestingly, although CD is known to be more prevalent in persons of North-European and Ashkenazi-Jewish genetic origin [8], a recent population-based study from Korea demonstrated the incidence of CD has increased from 0.05 in 1986 to 1.34 in 2005 [9]: the incidence of CD in non-Western populations is now approaching those seen in Western countries, although Asians with IBD may require surgery less often [10].

The proportion of elderly patients with CD varies in population-based studies from 5.9 to 30.7% [3] with a mean of 16.0% [11], the age of late-onset being variably defined as 50–60 years of age. A recent population-based series from Stockholm, Sweden noted an increase in the proportion of elderly patients (≥ 60 years) from 3.4 to 12.0% between 1955 and 1989 [12]. Similarly, in a study from Olmsted County, Minnesota, the incidence increased from 3.0 from 1940 to 1949 to 10.8 from 1990 to 2000 [1]. Considering this rise in incidence, combined with an increased overall life expectancy, we anticipate a significant increase in the prevalence of CD in the elderly in the coming decades.

TABLE 66.1 Summary table

- It is estimated that >1.1 million North Americans suffer from inflammatory bowel disease of which approximately 15% are over the age of 60 years
- Population-based studies suggest that the incidence of inflammatory bowel disease is increasing, including in the elderly
- The diagnosis of inflammatory bowel disease that presents in the elderly may be confused with other age-related colonic pathologies such as diverticular disease and ischemic colitis, but elderly patients with IBD may be less likely than younger patients to require surgery
- The surgical approach to elderly patients with Crohn's disease who require surgery parallels the surgical approach to young patients
- The surgical approach to elderly patients with ulcerative colitis who require surgery is significantly different than in young patients, with age-related cancers, age-related comorbidities, age-related fecal incontinence, altered lifestyle and decreased life-span, and anticipated need for pelvic radiation, all more likely to contribute to a nonrestorative approach to proctocolectomy with permanent ileostomy
- A significant proportion of elderly patients with permanent stoma will experience a stoma-related complication
- Advanced age alone should not be an absolute contraindication to ileal pouch-anal anastomosis
- Advanced age alone should not be an absolute contraindication to laparoscopic colectomy
- Elderly patients who require surgery for IBD are at increased risk of postoperative complications relative to young patients

Ulcerative Colitis Incidence

Ulcerative colitis was recognized as early as 1859 by Samuel Wilks who first described ulcerative colitis in a young woman [8, 13]. Since then, CUC has been shown to have an incidence rate in North America ranging from 3.0 to 14.3, almost identical to that seen for CD [14]. Also similar to CD, the incidence of UC shows interesting geographic differences. There has been a stable incidence throughout Europe, and greater incidence of both UC and CD in northern Europe was confirmed by the European Collaborative Study on IBD (EC-IBD) [15]. Also paralleling CD, the findings of increased incidence of CUC in Asia have also been observed. The incidence of CUC in the Songpa-Kangdong district of Seoul, Korea ranged from 0.34 in 1986 to 3.08 in 2005, lower than that observed in the West, but nonetheless on the rise [9]. Similar results have been seen in Hong Kong, China [16]. However, incidence data for UC may be influenced by inclusion or exclusion of patients with ulcerative proctitis, as available data suggest this entity is more common in elderly individuals [17].

Population-based studies suggest that the proportion of patients with late-onset UC (defined variably as >50 to >70 years) ranges from 8.1 to 43.9% with a mean of 12.0%. The EC-IBD study also found that the age-specific incidence of UC decreases with age in women, but not in men, confirming reports by others [17, 18].

Unimodal vs. Bimodal Age Distribution

Although in the past many epidemiologic studies demonstrated a bimodal distribution in the age at diagnosis for both UC [19, 20] and CD [20], more recent studies have not and this postulate is currently considered controversial [1, 7, 21]. As this issue is particularly pertinent to elderly patients with IBD, in the following sections we review the evidence for and against bimodality.

In older studies, the first age peak (mode) typically occurred during the third decade, whereas the second varied between the age of 50 and 80 years. The reason for the observed bimodality was not known, although several theories have been proposed. One is that the two peaks represent two types of disease, or a differential effect of age on the underlying disease. The variation in the anatomic distribution of CD depending on the patient's age is an example of the latter: CD of the terminal ileum tends to present in young patients [22], producing a unimodal age distribution for small bowel CD, with a peak during the third and fourth decades [23]. Conversely, older patients tend to have purely colonic disease, and the second peak has been found to be comprised predominantly of elderly women with Crohn's colitis, often left-sided [24, 25].

Another earlier theory that misdiagnosis was responsible for the second peak has gained less credence with time. As Crohn's colitis and UC came to be recognized as distinct clinical and pathologic entities during the middle part of the twentieth century, some authors ascribed the second peak to misclassification of such other conditions as ischemic and infectious colitis [26]. That may possibly have been so at one time, as was well shown in a retrospective review by Brandt et al. [27], where of 81 patients >50 years with a diagnosis of colitis, only 14% were thought to have UC and 5% to have CD after further consideration; ischemic colitis was the diagnosis assigned to three-fourths of the series. However, even exclusion of ischemic colitis did not abolish the second peak in UC; the incidence of UC in the elderly appears to have continued to increase, not decrease, in the face of improved diagnostic ability.

In 1996, Shivananda et al. reported for the EC-IBD project. In that study, which included 2,201 patients from across Europe from 1991 to 1993, no bimodality for either CD or CUC was observed [21]. Similarly in 2007, Loftus et al. updated the Olmsted County, MN experience with IBD from 1940 to 2000 [1]. Regarding bimodality, this pattern was *only* observed in men with CUC, and this subgroup (i.e., men with CUC) presented later in life than women with CUC. Changes in smoking patterns over the decades may play a role in the etiology of these age and gender observations [28]. Further study will be needed to refute or corroborate the suggestion that both CD and CUC actually have a unimodal, and not bimodal, age distribution.

Presentation and Natural History

Presentation

Overall, the presentation of CD and UC in the elderly does not vary significantly from that in the young population. A review of the clinical features in patients more than 50 years of age with CD found abdominal pain (82%), diarrhea (70%), weight loss (56%), and rectal bleeding (26%) to be the most common presenting features [29]. Toxic dilatation at presentation was rare. However, the initial diagnosis of IBD in the elderly is more often incorrect (64% of patients older than 65 years versus 96% of younger patients [30]) or delayed (despite clinical characteristics similar to those in younger patients) because of confusion caused by a higher incidence of diverticular disease and cardiovascular disease [31]. This delay in final diagnosis may in part result in the higher observed complication rate, which is seen in elderly as compared with younger IBD patients (36% vs. 16%, respectively), and a higher mortality rate [30].

Natural History

There are conflicting reports on the natural history vis-à-vis surgical intervention for CD and UC in the elderly. Gupta et al. [32], in a series of patients with both CD and UC, found that few patients required operation. This concurred with the findings of Fabricius et al. [33], who found that in elderly patients with CD, the course of the disease was largely dependent on the site of the lesion. Most of those with distal ileal disease required laparotomy for obstruction, peritonitis, or to rule out carcinoma, but thereafter, the prognosis was good. In contrast, patients with colonic disease rarely required operation and were managed medically. This contrasted with findings from others [34, 35] where 40–91% of those with colitis required surgery.

The natural history in UC is also the subject of controversy. Jones and Hoare [36] found that elderly patients were admitted more often with their first attack and were more likely to receive intravenous steroids than younger patients, but none required emergent surgery, and mortality on follow-up was no greater than that expected in the general population of the same age. The prognosis was found to be the same as in younger patients. This differs from Brandt et al. [37], who noted that in a group of 11 patients with UC, two developed toxic dilatation, three underwent operation, and three died during the first admission, leading to the conclusion that the prognosis was worse in the elderly as compared with younger patients. This conclusion has been supported by a study that utilized the Nationwide Inpatient Sample which

found that IBD patients >65 had higher mortality (odds ratio 3.9, 95% confidence interval [2.5–6.1]) even after adjusting for comorbidities [4]. Thus, current evidence supports that the elderly with IBD may have an equivalent, and likely worse, prognosis as compared with younger patients.

Differential Diagnosis

The majority of elderly patients with IBD will present with classic symptoms such as weight loss, abdominal pain, or bleeding and may prompt a workup for, and confusion with, more common pathology such as diverticular disease, ischemic colitis, or colorectal carcinoma as mentioned in the section “Natural History.” However, due to effects of aging on physiology, elderly patients may present with atypical signs and symptoms. IBD should be considered during the evaluation of elderly patients with digestive complaints, particularly chronic diarrhea with or without bleeding. Symptoms in the elderly may not suggest IBD for reasons that include blunted response to pain, poor communication because of altered comprehension or hearing, fear of the medical system, and focus on cancer as the most likely cause of symptoms [11]. A delay in diagnosis is common in old patients with IBD and may result in inappropriate treatment and a higher rate of complications [4, 30].

The differential diagnosis of IBD in the elderly includes ischemic colitis, diverticular disease, infectious colitis such as *Clostridium difficile* colitis (antibiotic-associated colitis) or cytomegalovirus (CMV) colitis, and of course, colorectal and other cancers. Less common entities that should be considered are collagenous colitis, lymphocytic colitis, radiation enterocolitis, lymphoma, carcinoid, vasculitis, and drug-induced colitis [11]. Diagnostic evaluation is generally unaffected by age, although elderly patients may be more likely to have underlying renal insufficiency precluding intravenous contrast, especially in the face of dehydration. Nonetheless, prompt diagnostic evaluation may be particularly important in elderly patients who may present with atypical symptoms. Two particularly common sources of diagnostic confusion are ischemic colitis and diverticulitis.

Ischemic Colitis

A history of cardiovascular disease may suggest a diagnosis of ischemic colitis. Occasionally, there is difficulty distinguishing ischemia from IBD. Brandt et al., in a study of 81 patients, found that half were originally diagnosed with CD, UC, or nonspecific colitis, but on retrospective review, ischemic colitis was diagnosed in 75% of the series [37]. The authors raised the question as to whether such incorrect

diagnoses might explain why colitis is reported to behave differently in the elderly. It is known that ischemic changes may mimic UC or CD. Computed tomography (CT) scanning of the abdomen and pelvis may not be able to differentiate the etiology of colitis. The addition of CT angiography (CTA) to the diagnostic armamentarium may assist clinicians in ruling out macrovascular ischemic colitis by allowing visualization of the patency of the mesenteric arteries and veins without formal angiography, at a lower dye load than traditional angiography. If ischemic colitis is strongly considered, clinicians should consider nonintravenous CT initially, or followed by, or proceeding directly to CTA if ischemic colitis is strongly suspected.

Diverticulitis

In addition to often being confused with ischemic colitis, IBD in the elderly presenting as segmental colitis may also be confused with segmental colitis associated with diverticular disease (SCAD) [38, 39]. Distinguishing segmental CD with diverticula from pure diverticulitis may be difficult, as each may have abdominal pain, diarrhea, fistula, and abdominal mass; blood in the stool, especially if in small amounts and frequent, should suggest CD. Peppercorn et al. described eight patients with segmental chronic active colitis associated with sigmoid diverticula [40]. These patients were all over 60 years of age, and none had features of CD. Endoscopy reveals a characteristic appearance with patchy areas of hemorrhage in

the sigmoid colon; biopsy demonstrates focal chronic active colitis without granulomata. It is important to consider this differential diagnosis, as major complications may be increased following surgery for suspected diverticulitis in elderly patients with unrecognized CD [41].

Surgical Therapy

Many aspects of the surgical therapy of Crohn's disease and ulcerative colitis are similar. This is particularly true with regard to indications (especially emergent ones), preoperative evaluation, and preoperative preparation. There are many excellent book chapters and atlases that deal with operative details [8, 42] but few describe adjustments that must be considered when operating on the elderly patient. This section highlights factors that may influence decision making in the older patient. A summary of recent studies of Crohn's disease in the elderly is presented in Table 66.2.

Crohn's Disease: Indications for Elective Surgery

Despite advances in the medical therapy of Crohn's disease, most patients undergo surgical intervention at some point during their lifetime. The National Cooperative Crohn's Disease Study reported operative rates of 78% at 20 years

TABLE 66.2 Summary of recent studies of Crohn's disease in the elderly

Author	Institution	Year	Study design	Age (years)	Elderly (N)	Major findings/comments
Heresbach et al. [107] ^a	Hospital Pontchillou, France	2004	Population-based, comparative	≥60	63	Elderly with similar overall incidence, more colonic involvement, more likely to also have diverticular disease and granulomas, and had more easy-to-manage flares
Triantafyllidis et al. [108]	Saint Panteleimon, Greece	2000	Case-control	>60	19	Terminal ileal involvement most common. Elderly more likely to present with acute abdomen, had higher complication rate, and lower rate of surgery for perianal disease. No difference in postoperative recurrence patterns
Norris et al. [109]	University of Sydney, Australia	1999	Subgroup comparisons	>55	33	Bimodal age distribution. Elderly with more colonic involvement, fewer ileocecal resections, and higher rate of cardiopulmonary complications
Wagtmans et al. [110]	Leiden University, The Netherlands	1998	Case-control	>40	98	Elderly were less likely to present with abdominal pain, shorter time from symptoms to diagnosis, more likely to be misdiagnosed, had a shorter interval from diagnosis to first operation, and recurred faster but less frequently. In summary, CD in elderly with a more rapid onset and time course

^aHigh quality/recommended

and 90% at 30 years from diagnosis [43]. The form of this intervention is determined by the operative indication, extent of disease, and site within the gastrointestinal tract.

For CD, but not ulcerative colitis, the risk of surgery for non-neoplastic IBD decreases with increasing age at diagnosis, irrespective of disease distribution and history of cigarette smoking [44].

Fistulas and Abscesses

Fistulas and abscesses, hallmark manifestations of Crohn's disease, are the most common indications for surgical intervention. The presence of fistulizing disease, with or without accompanying abscess, was the reason for operation in 35% of 482 patients in an early series reported by Farmer et al. [45] More recent series, including multicenter studies, have confirmed the prominence of this complication as an indication for operation. The risk of developing fistulas is to some extent related to the site of the underlying Crohn's disease. Fistulas appear to arise more commonly from the ileocolic distribution; 44% occurs in patients with ileocolitis, compared with 32% in patients with more proximal small bowel distribution, and 23% in those with colonic disease alone.

Fistulas may develop between diseased bowel and any structure or surface adjacent to the inflammatory process. They may be internal or external. Internal fistulas may, for example, be classified as enteroenteric, enterocolic, enterovesical, or enterovaginal. External fistulas are enterocutaneous, perianal, and perirectal. Accompanying abscesses may be within the peritoneal cavity (enteroparietal), interloop, intramesenteric, retroperitoneal, or perianal.

Symptomatic fistulas generally require operative intervention. Corticosteroids rarely result in fistula closure. Fistulas have been demonstrated to heal in 30–40% of patients given 6-mercaptopurine [46] but only in the absence of obstruction. Similarly, the Food and Drug Administration (FDA)-approved antitumor necrosis factor- α antibody (anti-TNF- α) antibody infliximab has been shown to be efficacious in healing fistulas in up to 55% of patients [47]. Percutaneous drainage under antibiotic coverage is the first-line therapy for abscesses, followed by resection of the affected bowel. Long-standing fistula and chronic pelvic abscess cavities can harbor scirrhous type adenocarcinoma.

Obstruction

Obstruction is the second most common indication for operation; in one report, it occurred in 34% of patients undergoing

surgical therapy of Crohn's disease [45]. It is seen in 55% of patients requiring operation for small bowel disease, 35% where there is ileocolic disease, and 12% in patients with Crohn's colitis. Early obstructive symptoms may improve with steroid therapy, but longer-standing symptoms generally indicate a fibrotic stricture that does not respond to medical therapy. These long-standing strictures, especially colonic but also in the small bowel, are worrisome for harboring adenocarcinoma.

Carcinoma

There is an established association between Crohn's disease and carcinoma of the colon and the small bowel. The magnitude of this association is, however, controversial. Carcinoma complicating the inflammatory state can be difficult to recognize on preoperative radiologic studies and even macroscopically at operation. For this reason, it is advised that all sites of stricturing undergoing stricturoplasty, rather than resection, should be biopsied to exclude underlying malignancy. Resection of malignancy that occurs in a background of Crohn's disease unfortunately has poor results, particularly in the small intestine [48].

Refractory to Medical Therapy

In the absence of indications mandating prompt surgical therapy, patients with symptomatic Crohn's disease undergo medical therapy. The severity and extent of disease determine the role of sulfasalazine, 5-aminosalicylic acid (5-ASA) compounds, antibiotics, steroids, immunosuppressive drugs, and biologic agents such as anti-TNF- α antibodies. Operative intervention is indicated if the response to medical therapy is incomplete, side effects develop, or planned withdrawal of steroids, for example, is not possible once a response has been induced.

Indications for Emergency Surgery

Toxic Colitis

A diagnosis of toxic colitis mandates emergent treatment. One of the most useful definitions includes a subjective and an objective component [42]. Toxic colitis is defined as an acute "flare" of Crohn's disease accompanied by two of the following: fever ($>38.6^{\circ}\text{C}$), hypoalbuminemia (<3.0 g/dl),

leukocytosis ($>10.5 \times 10^9$ cells/l), tachycardia (>100 beats/min). Megacolon is additionally diagnosed by colonic dilatation of more than 5 cm. A low threshold of suspicion is important in the elderly, where age alone can mask classic abdominal symptoms and signs, even in the absence of steroids or immunosuppressive agents, which may also conceal symptoms.

Therapy should be instituted as soon as the diagnosis is suspected. Emergent operative intervention is necessary in the presence of perforation, peritonitis, sepsis, and massive hemorrhage. In the absence of these findings, medical therapy is initiated with intravenous rehydration, high-dose parenteral corticosteroids or other immunosuppressive drugs, bowel rest, and broad-spectrum antibiotics. A vital component of treatment is frequent serial abdominal examinations and abdominal radiographs. Deterioration during therapy is a further indication for operation, as is failure to improve after 5–7 days of conservative treatment, or 24–48 h in the case of megacolon. Surgical management should be pursued aggressively in the elderly, who have little physiologic reserve and are less well able to survive the consequences of colonic perforation.

Perforation

Free perforation is unusual but may occur in the setting of acute disease or chronic disease. With acute toxic colitis, perforation occurs in the presence of a dilated, friable colon with transmural inflammation. Perforation in patients with chronic disease occurs in the presence of an acute exacerbation of small bowel disease often in association with obstruction. Perforation occurs in fewer than 2% of patients with small bowel CD [49]. More commonly, the fistulizing nature of CD results in adhesions to adjacent loops of bowel that contain the process and prevent free perforation; an abscess so formed may itself perforate and result in purulent peritonitis or fecal peritonitis if there is a free connection to the bowel lumen.

Hemorrhage

Hemorrhage, a relatively unusual complication of CD, should be treated in a fashion similar to that for significant gastrointestinal bleeding due to other causes. The patient's condition should be stabilized while investigations proceed to determine the site of bleeding. Emergent operative intervention is indicated for persistent hemodynamic instability after transfusion with 4–6 units of blood, recurrent bleeding, or an additional indication for resection of the diseased bowel. The elderly, particularly those with coexisting cardiovascular disease, have little physiologic reserve, and early

operative intervention should be considered in those who have demonstrated unstable vital signs.

Preoperative Preparation

Completion of Workup

Initial studies are guided by the patient's symptoms. Once the primary site of Crohn's disease has been identified, the remainder of the gastrointestinal tract should be evaluated to identify the presence of coexistent sites of disease, which may determine the nature and extent of the operative approach. For example, the individual with obstructive-type symptoms may undergo a CT, CT-enterography, or small bowel series indicating ileocecal disease; the operative approach is different depending on whether the disease is localized or there is also coexistent extensive colitis demonstrated on colonoscopy. The Montreal classification of CD is especially useful in classifying the extent of disease (Table 66.3). Such information is important when discussing the nature of the operative approach, the extent of resection, and the likely postoperative course.

Preoperative Discussion

Knowing the extent and severity of disease assists in preoperative discussions with the patient and family. Procedure-specific risks should be discussed and tailored to the patient and to the procedure contemplated. Such risks may include bleeding with the attendant risks of blood transfusion, wound infection, anastomotic leak and possible abscess,

TABLE 66.3 Montreal (Revised Vienna) classification of Crohn disease

Category	Abbreviation	Description
Age (of diagnosis)	A1	<16 Years old
	A2	17–40 Years old
	A3	≥40 Years old
Location (pre-surgical)	L1	Terminal ileum
	L2	Colon
	L3	Ileocolonic
	L4 ^a	Upper gastrointestinal tract
Behavior	B1 ^b	Non-stricturing, non-penetrating
	B2 ^b	Stricturing
	B3 ^b	Penetrating

Source: Reproduced with permission, Can J Gastroenterol 2005;19 (Suppl A):5A–36A

^aMay be added to L1, L2, or L3 for synchronous disease (e.g., L2+L4= colon+upper)

^bMay add "p" as a perianal disease modifier (e.g., B3p=penetrating+perianal)

enterocutaneous fistula, or peritonitis, and the likelihood of the need for a temporary or permanent stoma. Comorbidities, more prevalent in the elderly, need to be thoroughly assessed, and increase the risk of operation and anesthesia and should be discussed with the patient.

Bowel Preparation

Recent level I evidence suggests that mechanical bowel preparations (MBP) can be safely omitted during elective colorectal resections and anastomoses as MBP may be associated with increased anastomotic leakage rates [50]. This has been postulated to be related to the presence of liquid (as opposed to solid) stool, or nutritional/metabolic/toxic alteration of the enterocolonic mucosa.

Currently, MBP is widely practiced and remains the standard of care. For elective MBP or for constipated patients, most commonly recommended is a clear liquid diet for 24 h preoperatively with 2–4 L of polyethylene glycol with oral rehydration the evening before surgery. Nil per os (NPO) after midnight is still routine despite evidence that clear liquids up to 4 h preoperatively increases gastric emptying and reduces the risk of aspiration, and important consideration in elderly patients who may be at increased risk of delayed gastric emptying.

The MBP regimen must be modified in the patient with obstructive symptoms and may include a longer period of clear liquids in addition to low volume cathartics such as milk of magnesia (30 cc), magnesium citrate, or phosphosoda. However, surgeons must be aware that phosphosoda, although generally well tolerated by most patients, is contraindicated in those with known renal impairment (such as the elderly), electrolyte abnormalities, cardiovascular disease, bowel obstruction or otherwise altered GI motility or permeability, and in the elderly in whom it has been associated with acute phosphate nephropathy [51]. Tap water or phosphosoda enemas may be more helpful, particularly in the presence of obstructive symptoms. Despite the now routine use of bowel preparation in the outpatient setting, selected elderly patients, particularly those with cardiac disease such as aortic stenosis, may require hospitalization to prevent dehydration and avoid dramatic fluid shifts.

Intravenous antibiotic preparation does not differ from routine bowel surgery and typically consists of a second- or third-generation cephalosporin (e.g., Cefoxitin), or a quinolone (e.g., Ciprofloxacin) with metronidazole and in the case of penicillin, quinolone, or metronidazole allergy, vancomycin is used. Antibiotics must be administered within ½ h prior to skin incision and redosed intraoperatively after 4–6 h, and in the absence of an indication for ongoing antibiotic treatment discontinued within 24 h postoperatively.

Steroid Preparation

Recent level I data suggests that with the exception of patients with primary diseases of the hypothalamic–pituitary–adrenal axis, stress-dose steroids may be safely omitted as long as the patient continues to receive their usual daily dose [52]. However, current standard of care is for perioperative stress doses of corticosteroids to be administered if the patient has been treated with steroids within the preceding 6 months, a common occurrence in IBD patients. Our current preference is to administer methylprednisone 40 mg IV on call to the operating room, 30 mg every 12 h for the next 24 h, and then 20 mg daily; an alternative regimen is 50 mg of hydrocortisone on call to the OR, then 50 mg every 12 h in the first 24 h, 25 mg every 12 h the 2nd day, 12.5 mg every 12 h (or equivalent of the patients' usual dose) on the 3rd day, and the equivalent of the patients' usual dose the 4th day. Continuation of the taper depends on the preoperative dose and duration of steroid therapy but generally occurs slowly over a period of 6 weeks.

Electrolyte and Nutritional Deficits

Appropriate preoperative testing may reveal abnormalities. Electrolyte derangements, anemia, dehydration, and coagulation deficits should be corrected in both elective and emergent settings. Correction of nutritional deficits, as evidenced by weight loss, hypoalbuminemia, and negative nitrogen balance, is controversial. The use of total parenteral nutrition (TPN) has been shown in some series to improve nutritional parameters but does not significantly reduce postoperative complications [53].

One randomized study of severely nutritionally depleted patients undergoing GI surgery, a category which often applies to IBD patients, demonstrated a reduction in postoperative complications when such patients received 10 days of enteral nutrition preoperatively [54]. In addition, one series [55] did show that the extent of small bowel resection was less in patients receiving preoperative TPN, but this finding is possibly of clinical value only in patients who would otherwise be at risk of short bowel syndrome.

Enterostomal Therapy

Preoperative preparation of the patient for a stoma is invaluable, regardless of whether an ileostomy or colostomy is being considered and whether it is to be temporary or permanent. Preparation consists of marking the abdomen preoperatively and patient education. Such marking guides the correct site of the stoma within the rectus muscle, away from bony prominences and skin creases and scars.

Preoperative education and counseling, preferably from an enterostomal therapist, is valued by patients.

Operative Principles

Resection, Stricturoplasty, Diversion, or Bypass

Resection, with the goal of preserving as much absorptive bowel length as possible, is generally the approach of choice in patients whose symptoms are sufficient to merit operative intervention. In elderly patients, the colon is the most common site of disease, and with rare exceptions, symptomatic disease is resected. The surgery may take the form of segmental resection with primary anastomosis with or without diverting ostomy for limited colonic disease, or a subtotal colectomy with or without anastomosis, or proctocolectomy and Brooke ileostomy. Controversially, some centers construct ileal pouch-anal anastomosis (IPAA) in the setting of known CD; at our institution, CD is considered an absolute contraindication to IPAA, especially in the elderly. With small bowel disease, the ileocecal region is often affected most severely and merits resection.

Stricturoplasty is generally employed in the small bowel to avoid resection. It is usually not necessary at a first operation but can be employed at subsequent procedures to widen the lumen of the bowel at short strictures, and multiple to many stricturoplasties may be performed concurrently. Although active Crohn's disease is left in situ by this method, it does not appear to increase the rate of subsequent reoperation and has proven invaluable for preserving small bowel length in patients who would otherwise be at risk of short bowel syndrome. Stricturoplasty is less commonly used at anastomotic strictures but can be useful in this situation. It is advisable to obtain frozen section biopsy of the stricture being left in situ, as although quite rare (less than 0.1%), small bowel cancer has been observed in strictures [56].

In rare cases, when a resection or stricturoplasty of the diseased segment cannot be safely performed, diversion of the fecal stream or enteroenteric (internal) bypass may be the only remaining options and used as temporizing measures to improve the patients' condition [42]. Specifically, in the case of phlegmonous involvement of vital (vascular) structures (e.g., the iliac artery and vein), several options exist including exclusion with proximal external diversion and distal mucus fistula construction (to avoid creating a closed loop), or internal bypass, which allows the fecal stream proximal to the diseased segment to be diverted to a healthy segment while allowing the area distal to drain normally. As the patients' condition allows these, temporizing may allow sufficient healing to occur to allow more definitive surgical options.

Extent of Resection: Macroscopic vs. Microscopic Margins

The extent of resection is essentially based on the surgeon's judgment at operation and the ability to recognize macroscopically diseased bowel. Typical small bowel disease is manifested by bowel wall thickening and induration; serositis and prominent vessels running on the surface of the serosa; "creeping fat" or encroachment of mesenteric fat over the bowel wall; and thickening along the mesenteric edge of the bowel (Figs. 66.1 and 66.2). Correlating with these changes in the bowel are a characteristic thickening of

FIGURE 66.1 Crohn's disease, gross specimen, terminal ileitis. Note the creeping fat, serosal hyperemia, mesenteric lymphadenopathy, and ileo-ileal fistulization.

FIGURE 66.2 Crohn's disease, sectioned gross specimen, terminal ileitis. Note the transmural inflammation, strictured lumen, and linear (cat-scratch) ulceration which are typically pathognomonic for Crohn's disease, as compared to ulcerative colitis.

the mesentery, with enlarged lymph nodes that may occur diffusely throughout the small bowel mesentery but are usually more prominent at sites of active disease. Establishing the extent of disease in the colon may be more problematic by inspection of the external appearance alone, and intraoperative colonoscopy may prove invaluable in such cases.

Adequate margins are obtained by resecting back to macroscopically normal bowel. Once a subject of controversy, radical margins of resection now are thought to sacrifice more functioning small bowel than is of benefit for reducing recurrence. Several retrospective series have demonstrated no relation between the presence of microscopic disease at resection margins and the rate of recurrence [57, 58]. Hamilton et al. [59] compared patients undergoing frozen section evaluation of margins with a group whose margins were judged macroscopically free of disease; at 10 years, the clinical recurrence rates were not significantly different (60 and 66%, respectively), nor were the reoperative rates (36 and 32%, respectively). More recently, a randomized prospective trial comparing macroscopically free margins of 2 cm versus 12 cm has revealed no difference in clinical or operative recurrence rates at 5 years [60]. The advent of postoperative medical prophylaxis with mesalamine, azathioprine, and other medications has made microscopic disease-free resection margins moot [61].

Type of Anastomosis: Hand sewn vs. Stapled

Standard surgical principles apply to the creation of any anastomosis, ensuring good blood supply, lack of tension, and correct orientation. Use of suturing or stapling techniques depends on the surgeon's preference. Recent level I data demonstrated that the anastomotic technique had no impact on postoperative outcomes [62], while a meta-analysis found side-to-side (linear stapled) anastomoses to be superior. This finding is especially relevant for surgeons who do not perform a high volume of hand-sewn anastomoses or who do not see a high volume of CD patients. As anastomotic staples are not intended to be hemostatic (least they induce tissue necrosis), it is important to check the suture line for excessive oozing.

Operative Approach: Minimally Invasive (Laparoscopic) Surgery

Laparoscopic (LAP) or minimally invasive surgery (MIS) techniques are being increasingly used for Crohn's disease, a disease that was once thought not to be compatible with the laparoscopic approach. Initial concerns centered on the inherent inflammatory nature of the disease, with its attendant thickened bowel and mesentery and frequent association with fistulas and abscesses, which can make even open surgery

challenging. As experience with the technique has grown to include hand-assisted laparoscopic surgery (HALS), the feasibility and benefits of this approach in selected patients are becoming even more apparent. To date, several randomized trials and a meta-analysis have demonstrated the benefits of a MIS resection for ileocecal and small bowel disease [63]. Although these procedures take longer to perform, patients had shorter lengths of stay and lower morbidity. The presence of fistulas and abscesses do not necessarily preclude a successful laparoscopic approach, this being possible in up to 75% of such patients. A similar success rate was demonstrated in patients who had undergone prior abdominal operations. The procedure results in statistically significant and clinically relevant benefits, with patients exhibiting less pain, more rapid resolution of ileus, and earlier discharge [64]. Similar benefits have been demonstrated after MIS colectomy for Crohn's colitis [66] and also in elderly patients. A case-control series from the Mayo Clinic [64] of laparoscopic resection versus matched open resection found in the former group that postoperative ileus resolved more rapidly, patients had fewer postoperative complications, and they were discharged sooner. In addition, a significantly larger percentage of patients in the laparoscopy group were discharged to their own homes and remained independent after operation, an important consideration in the elderly.

It is now understood that age alone is not a contraindication to laparoscopic colon and rectal surgery [66], and several studies have examined the benefits of laparoscopic colorectal surgery in the elderly. Law et al. reported on the outcomes in a series of 65 patients over the age of 70 compared with 89 patients who had undergone open surgery [67]. They found benefits typical of a laparoscopic approach including earlier return of GI function and earlier discharge, but also found that LAP elderly patients had fewer cardiopulmonary complications. Similarly, Frasson et al. reported the results of a subgroup comparison from a randomized study of laparoscopic colorectal surgery of which 201 were >70 years of age [68]. They also found that the benefits of laparoscopic surgery are more pronounced in elderly patients; specifically, elderly patients who underwent LAP had lower morbidity and short lengths of stay. Although care must be taken to assess the impact of pneumoperitoneum on the cardiopulmonary comorbidities frequently seen in the elderly, clearly age alone is not a contraindication to LAP, and at our institution, is the preferred approach.

Management by Anatomic Site

Gastric and Duodenal Disease

Primary gastric disease is an unusual manifestation of CD [69]. Endoscopy may reveal gastric dilatation and superficial

ulceration. The findings may be suggestive of peptic ulcer disease or may be difficult to distinguish from carcinoma. Biopsy may reveal characteristic granulomas. Patients may undergo gastrectomy if carcinoma cannot be excluded.

The duodenum may be the site of primary or secondary manifestations of CD. Primary CD is unusual; the early non-specific symptoms are suggestive of peptic ulcer disease and may respond to antacids and systemic treatments for CD such as corticosteroids, immunomodulators, and biologic agents. In terms of definitive surgical management in the era of proton pump inhibitors, laparoscopic gastrojejunostomy with or without vagotomy has become an attractive alternative to open gastrojejunostomy and in experienced hands is the procedure of choice [70] for the palliation of CD-related gastric outlet obstruction. The omission of vagotomy (in lieu of PPI treatment in the face of complications) or performing a highly selective vagotomy prevents the marginal ulceration associated with bypass alone and avoids the postvagotomy diarrhea associated with truncal vagotomy. Duodenal strictureplasty is technically challenging and rarely performed, even in tertiary referral centers.

More commonly, the duodenum may be secondarily affected as a bystander adjacent to fistulizing disease in the ileum or colon, especially from a previous ileocolic anastomosis. This complication may be reduced by performing an ileoascending anastomosis, preserving as much of the right colon as possible at the time of ileocecal resection. The omentum should be used whenever possible to separate the anastomosis from the duodenum. Bystander duodenum may be closed primarily in a transverse manner.

Jejunioileal Disease

Manifestations of CD in the small bowel may be localized or diffuse. Most commonly, localized disease occurs distally and is generally amenable to resection, particularly at first operation. This also holds true for several segments of disease concentrated in one area, where a single resection and anastomosis is preferred rather than several anastomoses. Although sparing of the terminal ileum is relatively unusual with distal ileal disease, the ileocecal valve should be preserved if there is a distal disease-free area of more than 5 cm allowing an anastomosis to avoid ischemia to the anastomosis.

Surgical judgment faces stronger challenges in the event of diffuse small bowel disease. Occasionally, areas of small bowel dilatation serve as guides to points of significant stricturing, but often with diffuse disease, it is difficult to distinguish small bowel that is thickened secondary to CD from bowel that is thickened from chronic obstruction proximal to a stricture. In such instances, it is helpful to make an enterotomy distally and perform direct enteroscopy to evaluate the proximal bowel. An alternative is to insert a Baker

tube (a long tube bearing an inflatable balloon near its tip) proximally as far as the ligament of Treitz. The balloon is then inflated to a diameter of 1.5–2.0 cm and withdrawn slowly. The balloon is held up at points of stricturing that can be marked with seromuscular sutures, and stricturoplasties are performed at these sites.

Ileocecal Disease

Ileocecal disease is the commonest indication for operative intervention in all patients but is less common in older than in young patients. Frequently, the right colon is affected only to the level of the ileocecal valve, and it is possible to perform an ileoascending anastomosis, preserving most of the right colon.

Colonic Disease

The surgical approach to colonic disease is determined primarily by three factors: extent of disease (localized or diffuse), presence of rectal sparing, and function of the anal sphincter in preserving continence.

Localized Colitis

Among patients with disease limited to the colon, only 10% [71] exhibit limited or segmental disease of the colon. Unlike the situation with the small intestine, segmental resection of the colon was in the past considered controversial because of the impression that recurrence rates were high and that an ileostomy would ultimately be required [42]. A series from the Mayo Clinic [72] of 49 patients undergoing limited colonic resection for segmental disease showed that only 14% of patients over a mean follow-up period of 14 years ultimately required stoma construction. Those who ultimately required a stoma enjoyed a mean stoma-free interval of 23 months. Thus, a stoma was avoided in most of the patients. Even those in whom a stoma was eventually necessary benefited from an extended period of stoma avoidance. Social and body image arguably may be of more importance to young patients for avoiding a stoma. The elderly also benefit from this approach, particularly those in whom a previous small bowel resection has been performed and who potentially might be debilitated by profuse small bowel effluent through an ileorectal anastomosis or an ileostomy. The use of segmental colonic resection may increase with more widespread prescription of immunosuppressive drugs, such as azathioprine or 6-mercaptopurine for diffuse colitis; areas of most severe ulceration appear in some instances to heal with focal stricturing.

Diffuse Colitis

In the elective setting, the choice of procedure for treating pancolitis is determined in part by the presence or absence of rectal disease. In the patient with proctocolitis, the preferred option is proctocolectomy and Brooke ileostomy. Although some have suggested use of a low Hartmann closure of the rectum to allow perianal disease to regress, 40% of the patients (10/25) required a later perineal proctectomy, and three of these patients still exhibited wound problems [73]. The use of ileostomy alone improves general well-being in about two-thirds of patients but does not consistently avoid later proctocolectomy, and fewer than 10% ever experience restoration of intestinal continuity. Diversion alone may be a consideration in an elderly patient who refuses or who would not tolerate proctocolectomy.

The elderly patient with pancolitis but rectal sparing deserves careful evaluation. Measurement of anal canal pressures is not predictive of postoperative function, although Keighley et al. [74] found assessment of rectal compliance (by identifying those whose maximum tolerated rectal volume was >150 ml) to be helpful. The individual who remains continent despite loose stool during attacks of colitis has undergone the most rigorous physiologic test of continence and would be a candidate for total abdominal colectomy (subtotal colectomy) with ileosigmoid or ileorectal anastomosis. Those occasionally incontinent of loose stool probably have less than perfect control, but this situation may be preferable to having a stoma; it merits discussion with the patient. The individual who is frankly incontinent would be best served by a proctocolectomy or a subtotal colectomy, ileostomy, and retained rectal stump. Although some authors have suggested use of an ileal pouch to improve compliance if resection is necessary to the level of the mid-rectum [42], this procedure is highly controversial, as known Crohn's disease is widely considered an absolute contraindication to use of a pouch, given the 45% risk of pouch failure secondary to complications [75].

In the emergent setting, the guiding principle is to remove the site of disease as expeditiously as possible, avoid further complications, and perform a later staged procedure if necessary. In the setting of diffuse colonic involvement and megacolon, perforation, or hemorrhage, a subtotal colectomy with ileostomy is performed, and the rectum is either left long as a mucus fistula or short as an extraperitoneal stump. If hemorrhage is arising from the rectum in the face of diffuse disease, however, proctocolectomy cannot be avoided. Perforation resulting from localized disease in the colon is addressed with resection, proximal stoma, and mucus fistula or exclusion of the distal bowel. Perforation of localized rectal disease is approached by proximal colectomy and drainage of the pelvis, with proctectomy 3–6 months later.

Perianal Disease

Crohn's disease manifestations in the perianal region include skin tags, fissures, ulcers, abscesses, fistulas, and anorectal stricture. These findings frequently occur after intestinal symptoms have resulted in a diagnosis of CD, but when perianal findings precede other symptoms, the diagnosis can present difficulties. Examination includes digital assessment, anoscopy, and rigid or flexible sigmoidoscopy. Discomfort may necessitate examination under anesthesia for full evaluation. Biopsy infrequently yields evidence of a granuloma, but other features are suggestive of CD: edematous, violaceous skin tags; fissures at sites other than the midline; indolent abscesses; complex fistulas; and stricturing without evidence of malignancy or prior anorectal surgery. A new diagnosis of CD should prompt evaluation of the entire gastrointestinal tract, although it is unclear whether disease activity more proximally affects perianal disease [76].

Therapy must be individualized, bearing in mind treatment principles of relief of symptoms and avoidance of additional complications. Careful consideration should be given to appropriate medical and surgical approaches. Perianal skin tags and hemorrhoids are best approached conservatively, with control of diarrhea, sitz baths, and analgesia; surgical therapy of either is associated with a high rate of poor outcomes [77]. Symptomatic fissures should be evaluated to rule out underlying sepsis and then approached initially with medical therapy. In selected cases and when conservative therapy has failed, lateral internal sphincterotomy may be beneficial. Careful consideration must be given to issues of continence, however, particularly in the elderly. Abscesses should be treated with incision and drainage, making the incision into the abscess cavity as close to the anus as possible to keep any subsequent fistula as short as possible.

Management of perianal fistulas is often challenging. As with other situations, therapy is aimed at relieving symptoms; hence, in the absence of associated sepsis, an asymptomatic fistula may require no specific therapy. Simple low fistulas without accompanying proctitis may be managed successfully with fistulotomy [78], particularly when combined with therapy such as metronidazole or sulfasalazine [79]. When it is thought that sphincterotomy may result in fecal continence because the fistula is high or complex or because the elderly patient has borderline continence, other approaches are necessary. Noncutting setons achieve drainage without compromise of continence; despite the presence of a foreign body, most patients tolerate setons far better than undrained fistulas, particularly if the seton is of a soft material such as Silastic vessel loops [42]. If the rectal mucosa does not exhibit active disease, the patient may be a candidate for a rectal mucosal advancement flap. An overall success rate of 60% has been reported for this approach to low fistulas [80], but the success rate falls to approximately one-third in high,

complex fistulas [81]. An alternative approach is the use of fibrin glue, which has a lower success rate than with non-Crohn's fistulas after a single application, but repeated applications may result in success and there is no risk of compromising the sphincter. Although anti-TNF-Ab therapy (infliximab) is showing promise in therapy of perianal CD that would otherwise be considered an indication for proctectomy; data in the elderly are still limited or absent. Creation of a diverting ileostomy is occasionally a useful means for controlling severe perianal disease, but only one-third of patients ever achieve successful reversal [42].

Ulcerative Colitis: Indications for Elective Surgery

Failure of Medical Therapy

An algorithmic approach to the surgical management of CUC is presented in Fig. 66.3. Medical therapy may be considered to have failed when maximal therapy has not controlled symptoms or when symptoms are abolished only at the expense of side effects from the medications themselves. The inability to wean steroids completely or to an acceptable level is also an indication for operation. Inability or unwillingness to comply with a medical regimen may prompt surgical intervention.

Presence or Risk of Carcinoma

An increased risk of colorectal cancer has been documented in those with extensive long-standing ulcerative colitis

[82, 83]. The magnitude of this risk is controversial, with population-based studies suggesting that the risk is lower than previously thought and most dependent on the extent and duration of colitis. It is best defined in patients whose disease onset occurred during childhood or the teenage years, those with extensive disease, and those whose duration of disease is more than 10 years; in these patients, the risk of developing cancer is reported to be 2% per year [84]. The risk in patients with later age of onset is not well defined. Monitoring by screening colonoscopy for dysplasia has limitations, including patient compliance and the finding that carcinoma may not have evidence of preceding dysplasia [85]. At the time of colectomy for dysplasia, more than 50% already have invasive cancer [86]. In the absence of an absolute indication (i.e., stricture, evidence of dysplasia or a dysplasia-associated mass, existing cancer [87]), the role of surgery is less clear, despite results of a decision analysis that suggest prophylactic colectomy improves survival more than surveillance [88]. In the elderly, later onset of disease and shorter duration of remaining life compared with younger patients probably results in surgery being used more for specific indications than for prophylaxis.

Indications for Emergency Surgery

Fulminant Colitis

The definition of fulminant colitis is identical to that described for CD, although the Truelove and Witts' criteria may be useful in stratifying disease severity in CUC (Table 66.4) [89]. It is important to remember, particularly in the patient presenting with a fulminant first attack, that the differentiation

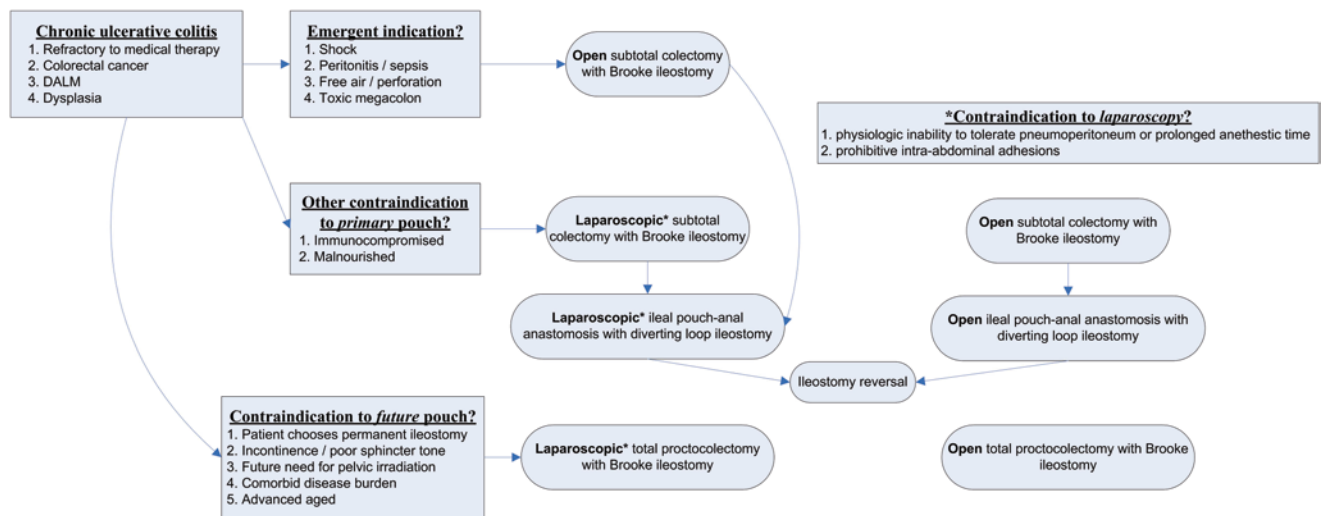

FIGURE 66.3 Surgery for elderly patients with chronic ulcerative colitis treatment algorithm.

TABLE 66.4 Modified Truelove and Witts' criteria of ulcerative colitis disease severity [89, 111]

Variable	Mild disease	Moderate disease	Severe disease	Fulminant disease
No. stools (per 24 h)	<4	4–6	>6	>10
Blood in stool	Intermittent	Occasional	Frequent	Continuous
Temperature (°C)	Normal	>37.5	>37.5	>37.5
Pulse (beats/min)	Normal	>90	>90	>90
Hemoglobin	Normal	Anemia	<75% of normal	Transfusion requirement
ESR (mm/h)	<30	–	>30	>30

between CD and UC may not be possible. The surgical approach is the same, whichever the underlying diagnosis. Although this diagnosis previously has been associated with a high mortality rate, mortality is now less than 3% [90] due in part to aggressive surgical intervention and probably to changes in medical management.

Toxic Megacolon, Perforation, Hemorrhage, Obstruction

In emergent settings, UC is often indistinguishable from CD. The principles of therapy outlined for CD, including the appropriate extent of resection in emergent settings, apply equally to either diagnosis.

Preoperative Preparation

Many of the principles of preoperative preparation discussed for patients with CD apply equally to those with UC. They include correction of electrolyte abnormalities and severe anemia, bowel preparation, use of antibiotics, and stress doses of steroids. Possibly, the most important aspect differentiating the patient with UC from the one with CD is consideration given to reconstructive surgery in the form of the ileal pouch-anal anastomosis (IPAA), which should be avoided in the acute setting.

Operative Procedure

Essentially, the choice of procedure (Table 66.5, Fig. 66.3) depends on the presentation of the patient (e.g., disease severity) and how much of the rectum is to be removed (all, part, or none), and if the anal sphincter is competent.

If the patient is incontinent of stool due to an incompetent sphincter (and not to poor compliance in a diseased rectum), the decision is simple: proctocolectomy and Brooke ileostomy. In the individual without compromise of the sphincter, consideration may be given to proctocolectomy and ileostomy, subtotal colectomy, (Fig. 66.4) and ileorectal anastomosis, or proctocolectomy, and IPAA (or ileal pouch-distal rectal anastomosis).

Multiple studies have examined the role of restorative proctocolectomy in the elderly [91–102]. These have been summarized in Table 66.6. Advanced age has generally been considered a contraindication to IPAA because of the high risk of fecal incontinence in the elderly. The clinical results in carefully selected patients over the age of 50, however, are equivalent to those of younger patients. Anal sphincter strength does decline after the age of 70 [103], and few, if any, patients beyond this age are candidates for this operation.

Operative Approach: Minimally Invasive (Laparoscopic) Surgery

Similar to as seen in CD, MIS techniques are being increasingly used in CUC. Several recent studies from Mayo Clinic have demonstrated the applicability of MIS techniques to CUC, including subtotal colectomy, IPAA, TPC with BI [104–106]. In a case series of 50 patients with severe-to-fulminant CUC who underwent MIS subtotal colectomy with Brooke ileostomy, the majority (95%) who subsequently underwent IPAA were performed laparoscopically with a median length of stay of 4 days for each procedure. Similarly in a case-matched study comparing open and LAP IPAA, the benefits typical of a LAP approach were demonstrated. Finally, in a case series of 43 patients who underwent MIS TPC-BI, and in whom the median age was 66 years, this procedure was demonstrated to be safe and feasible. Our preferred port placement for both LAP and HALS approaches to colectomy for CUC is shown in Fig. 66.5.

TABLE 66.5 Choice of operation for ulcerative colitis in elderly patients

Typical no. of stages	Procedure	Contraindications	Comments
3-, 2-, or 1-stage ^a IPAA	TPC with IPAA and DLI; 3-stage if follows STC with BI, rarely, if ever 1-stage without DLI	Incompetent sphincter Advanced age (relative) Need for pelvic irradiation	Risks related to multiple operations and general anesthetics Complete excision of disease Risk of pouchitis Risk of cancer in retained mucosa
2-Stage (modified) IPAA	STC with BI followed by IPAA <i>without</i> DLI	None	Easier/faster operation to perform Complete excision of disease Risk of pouchitis; increased risk of leak? Risk of cancer in retained mucosa
1-Stage ^a	TPC with BI	None	Easier/faster operation to perform Complete excision of disease Risk of stoma-related complications
2-, or 1-stage	TPC with IRA (straight IRA or ileal pouch-rectal anastomosis); infrequently 2-stage with DLI	Incompetent sphincter Advanced age (relative) Need for pelvic irradiation Noncompliant for follow-up	Easier/faster operation to perform Risk of pouchitis Increased risk of cancer in retained rectal mucosa
2-, or 1-stage	TPC with K-pouch; 2-stage if follows STC with BI	Most patients	Frequent reoperation Rarely recommended, even in young patients
2-, or 1-stage	STC with IRA; infrequently 2-stage with DLI	Incompetent sphincter Active rectal disease Noncompliant for follow-up	Incomplete excision of disease At risk for proctitis or development of rectal cancer
2-, or 1-stage	STC with BI	None	Easier/faster operation to perform Incomplete excision of disease At risk for proctitis or development of rectal cancer
2-, or 1-stage	Segmental colectomy with primary anastomosis	Most patients	Rarely if ever recommended due to incomplete excision of disease, even in young patients
Temporizing procedure	Turnbull procedure (ileostomy with blowhole colostomy)	Almost all patients	Generally of historic interest only for the treatment of toxic megacolon in unstable patients; however, success with this procedure has recently been reported in 2 pregnant women with toxic megacolon [112]

TPC total proctocolectomy, BI Brooke ileostomy, DLI diverting loop ileostomy, IPAA ileal pouch-anal anastomosis, IRA ileorectal anastomosis, STC subtotal colectomy, K-pouch continent ileostomy (Kock pouch)

TABLE 66.6 Summary of recent studies of ileal pouch-anal anastomosis in the elderly

Author	Institution	Year	Study design	Age (years)	Elderly (N)	Major findings/comments
Ho et al. [102] ^a	Cleveland Clinic, Florida	2006	Subgroup comparisons	>70	17	No difference in length of stay, complications (40%), or pouch failure between >70 and <70 years old cohorts
Chapman et al. [101]	Mayo Clinic, Rochester	2005	Subgroup comparisons	>55	65	No difference in complications. Incontinence more common, but did not affect QoL
Longo et al. [99] ^a	St. Louis University	2003	Population-based (Veterans) subgroup comparisons	>50	158	Of 46 patients >70 years, no IPAA's were performed. 22% overall surgical morbidity; 4% mortality (all non-IPAA patients)
Delaney et al. [100] ^a	Cleveland Clinic, Ohio	2003	Subgroup comparisons	56–65 >65	154 42	Increased incontinence, night-time seepage in older groups; QoL decreased but not statistically
Farouk et al. [97] ^a	Mayo Clinic, Rochester	2000	Subgroup comparisons	>45	204 (1 year) 33 (12 years)	At 1 and 12 years, incontinence affected older group more often. Incontinence increased with time in older, but not younger, patients. Pouch excision due to incontinence not statistically different between group (<45, n=11 vs. >45, n=3)
Church [98]	Cleveland Clinic, Ohio	2000	Case report, 10-year follow-up	85	1	Bowel function, QoL remained relatively stable; age is not necessarily a contraindication to IPAA
Takao et al. [96]	Cleveland Clinic, Florida	1998	Subgroup comparisons	>60	17	Postoperative minor and transient functional impairment is not an age-related phenomenon
Tan et al. [95]	Queen Elizabeth Hospital	1997	Subgroup comparisons	>50	28	Included 4 non-CUC patients. Higher incidence of IPAA stenosis in the elderly. Age did not impact functional outcomes
Bauer et al. [94]	Mount Sinai	1997	Subgroup comparisons	>50	66	Elderly group with longer duration of disease, more dysplasia. Age did not impact functional outcomes
Reismann et al. [93]	Cleveland Clinic, Florida	1996	Subgroup comparisons	>60	14	Older patients experience more nocturnal movements (2 vs. 1.1, $p<0.05$) than younger patients. Morbidity and manometry did not differ
Jorge et al. [92]	Cleveland Clinic, Florida	1994	Subgroup comparisons	Mean 56	22	Transient, statistically significant decrease in internal anal sphincter function in older group, but recovered completely
Lewis et al. [91] ^a	General Infirmary, Leeds	1993	Matched case-control	>50	18	Anorectal manometry not statistically different between age groups before/after surgery. Age alone is not a contraindication to restorative surgery if anal sphincter is completely intact

^aHigh quality/recommended

CASE STUDY: REFRACTORY ULCERATIVE COLITIS IN AN OCTOGENARIAN

An 83-year-old male with a 2-month history of CUC presented to the surgical service with refractory colitis despite 5-aminosalicylate dose escalation and 30 mg of prednisone daily. The patient complained of 8–14 bloody bowel movements per day. The patient's body mass index was 25 kg/m². The patient had multiple comorbidities including steroid-induced diabetes mellitus, chronic renal insufficiency, hyperlipidemia, iron-deficiency anemia, and a history of a type 5 peptic ulcer disease. Preoperatively, the patient's Charlson score was 8 points, and American Society of Anesthesiology (ASA) score was 3. The patient has a history of a radical prostatectomy with postoperative external beam irradiation. Endoscopy revealed moderately active pancolitis with no evidence of dysplasia. Given the patient's age, comorbidities, and history of pelvic surgery and irradiation, we recommended a total proctocolectomy with end ileostomy.

The patient underwent an uneventful laparoscopic total proctocolectomy, intersphincteric dissection, and Brooke ileostomy. Given the history of pelvic surgery and irradiation, the pelvic dissection was tedious; overall operative time was 444 min, estimated blood loss was

450 ml, and he was transfused one unit of pack cells. There were no intraoperative complications, and the procedure was completed laparoscopically. Gross pathology revealed severely active pancolitis with a tubular adenoma with low-grade dysplasia in the descending colon.

Postoperatively, the patient's stoma began functioning on day 3, and he tolerated a regular diet. The patient was discharged home on postoperative day 4 but 2 days later returned to the hospital with left lower extremity swelling and was found to have an ileofemoral deep vein thrombosis, treated with anticoagulation. He suffered no other complications within 30 days. Subsequently, the patient had developed a partial small bowel obstruction related to a parastomal hernia, which was initially managed with a hernia belt. The hernia was enlarged, and the patient underwent an uneventful mesh repair and remains asymptomatic.

This case demonstrates that:

1. Age alone is not a contraindication to laparoscopic colectomy (nor is it an absolute contraindication to IPAA).
2. Prior treatment of age-related cancers may affect surgical decision making and recommendations for restorative proctocolectomy.

(continued)

CASE STUDY (continued)

3. The timing of surgical intervention for elderly patients with moderate-to-severe CUC must take into account the patients physiologic reserve and ability to tolerate ongoing bloody diarrhea. In the face of worsening anemia, renal insufficiency, a lower threshold for operation may be appropriate for elderly patients with active CUC.
4. The risks and benefits of surgical therapy for elderly patients with CUC must be weighted against the risks and benefits of escalated medical therapy with agents such as corticosteroids and infliximab. These agents in particular may be associated with increased postoperative infectious complications and less well tolerated in elderly, as compared with younger patients.
5. Elderly patients with long-standing IBD colitis are likely to be at increased risk of inflammatory-associated cancer.
6. A 1-stage procedure with permanent ileostomy may obviate the need for subsequent planned operations, but this advantage must be weighted against the long-term risk of stoma-related complications and need for reoperation.

Chapter 67

Diverticulitis and Appendicitis in the Elderly

Scott C. Thornton

CASE STUDY

MS is a 90-year-old woman with no significant comorbidities who lives on her own at home. She was hospitalized five times over 4 months with an initial diagnosis of unrelenting ischemic colitis of the descending colon. This was diagnosed by multiple CT scans and with endoscopic confirmation. Despite antibiotics and enteral supplementation, she had slow and progressive weight loss and increasing inability to eat. Indication for operation was failure to progress with medical therapy and inability to eat. Her albumin, prealbumin, and initial weight were 2.0, 9, and 92 pounds, respectively. She underwent a left colectomy with primary anastomosis and protective loop ileostomy. Operative finding, confirmed by pathologic examination, was retroperitoneal perforated diverticulitis

with contained abscess (Hinchey class II). Her postoperative course was complicated by ileostomy dysfunction, resulting in watery diarrhea, which caused dehydration and electrolyte imbalance. She developed a lower extremity deep venous thrombosis and was started on warfarin after a vena cava filter was placed. After a single 5-mg dose of warfarin, her INR rose to ten, and she had a spontaneous intra-abdominal bleed requiring transfusion. Aging does not alter the pharmacokinetics of warfarin but may increase sensitivity to its anticoagulant effects. She was unable to eat due to newly diagnosed, severe esophagitis. This was treated medically, and a PEG was placed for enteral nutrition. She was ultimately discharged to an extended care facility 1 month after surgery. She maintained mental acuity throughout her illness and is anxiously awaiting the reversal of her ostomy.

Elderly patients are often difficult to be correctly diagnosed due to nonroutine presentations. Once treated, they more frequently have complications with medical therapies aimed at cure. The following case presentation illustrates many of these problems found when treating older patients.

This chapter deals with diverticular disease and appendicitis in the elderly. Diverticular disease increases in incidence with age and also appears to present with diffuse peritonitis more frequently in old than in young patients. Acute appendicitis in the elderly accounts for 5–10% of all appendicitis,

and old patients tend to present more frequently with advanced disease than do young groups. There is good evidence that the elderly present more frequently in an atypical fashion with both of these diseases compared with their younger counterparts. Abdominal pain may be absent or not greatly perceived in older patients. Physiologic responses to stress and infection are also blunted in the elderly. Older patients are burdened with more comorbid conditions and less mental and physical reserves compared with their younger counterparts. Furthermore, it is well known that emergency operations in the elderly are associated with significantly higher mortality and morbidity rates than similar operations on younger patients. Thus, old patients present atypically, often with more advanced disease and have higher complication and death rates than the young. This chapter attempts to explain these findings.

Diverticular Disease

Etiology

Diverticular disease is the fifth most costly digestive disease in the USA [1]. The cause of diverticulosis is unknown. Colonic diverticula are mucosal (and submucosal) herniations through the muscle wall of the colon. The sigmoid colon is affected in 96% of patients, with this area being the only site of diverticulosis in two-thirds of patients [2]. Acute diverticulitis can occur anywhere in the colon and has been reported in the rectum [3, 4]. Diverticula occur at the points of weakness where the blood supply to the mucosa penetrates the bowel wall. Most commonly, they occur between the mesenteric and antimesenteric taenia coli. Less commonly, they occur between the two antimesenteric taenia. Strong epidemiologic evidence suggests that a low-fiber diet has a substantial etiologic role in the development of diverticulosis [5, 6], and low-fiber intake has long been implicated as a cause of diverticulosis [5, 7]. In the USA, the incidence of diverticular disease has increased with decreasing fiber intake [8]. Vegetarians have been found to have a lower incidence of diverticular disease than nonvegetarians [9]. Other studies have confirmed these findings [10–14].

The current speculation is that a diet low in fiber decreases stool bulk. This in turn causes narrowing of the colonic lumen, prolongs intestinal transit time, and increases intraluminal pressures. Painter et al. [15] combined manometry and cineradiography and found that the increased intraluminal pressure may be due to simultaneous contractions of circular muscular bands causing occlusion of short segments of bowel. Contraction rings are thus formed in the sigmoid colon, which produces “segmentation” of these short segments of bowel. Contraction of the muscle wall of these sections can result in intraluminal pressures of 90 mmHg or more. This pulsion pressure may lead to mucosal herniation along the weak points of the bowel wall, resulting in diverticula. Others have found that the contractile response to eating is exaggerated in people with diverticulosis [16]. Although consistent with the speculation that elevated pressures are particularly significant in combination with or potentiated by low-fiber stools, experimentation with colomyotomy showed that decreased muscular activity did not affect intraluminal pressures [17]. Stool bulk may be related to intraluminal pressure only in that stool bulk increases the radius of the colon, thereby decreasing wall tension. Painter et al. suggested that a low-fiber diet causes a narrower colonic lumen, which allows the colon to segment more efficiently, increasing the segmental intraluminal pressures [15]. Low-fiber diets in rats has been shown to result in diverticulosis in 45% of subjects compared with only 9% in a group fed the highest fiber diet [18]. Further, a large, longitudinal study of

males in the USA revealed a relatively straight line correlation between fiber intake and diverticular symptoms [19]. Exercise may also have a protective effect on the development of symptoms from diverticular disease [20].

Colonic dysmotility may contribute to diverticular disease. Abnormally slow wave patterns have been found in patients with symptomatic diverticular disease [21]. Furthermore, patients with symptomatic diverticular disease return to normal motility patterns with ingestion of bran, whereas those with asymptomatic diverticulosis have no change in motility with bran intake [22]. Others have disputed these findings [23]. Colonic transit times can be decreased by adding bran to the diet [24–26], and water-retaining fiber can decrease intraluminal pressure [27]. These findings lead to dietary modifications in attempts to alleviate diverticular symptoms.

One report [28] implicated localized ischemia as a causative factor for antimesenteric free perforation of the colon from diverticulitis. In patients with multiple bilateral pseudo-diverticula arranged in a double row about the antimesenteric taenia, the vascular supply to the middle area of the antimesenteric wall is compromised. Careful histologic studies showed that free perforation associated with diverticulitis has the same histologic characteristics as ischemic bowel perforations. It is well known that microvascular changes predisposing to microvascular ischemia occur in the elderly. The more aggressive disease and higher perforation rates found in the elderly [29–32] may be related to this ischemic process. Perhaps this is the reason why the elderly have higher free perforation rates when compared with younger patients.

Investigators have also touched on whether an intrinsic change in bowel wall composition is necessary for the development of diverticula. Young people with collagen vascular diseases such as Marfan’s syndrome [33] have been reported with diverticular disease. Several authors have also documented an association of diverticular disease with degenerative disorders such as varicose veins [34], hiatal hernias [35], and arthritis [36]. The most important element with regard to strength of the colon wall is collagen [37]. Collagen fibrils in the left colon become more numerous but smaller in width with age, and this difference is greater with diverticular disease [38]. Similarly, elastin fibrils increase in number but decrease in quality with age [39]. Pace [39] found that colon wall thickness increases with age and is thickest in the distal colon. These factors combined to result in decreased tensile strength and decreased expandability of the aging colon wall [40]. Electron microscopic examination reveals that there is a two-time increase in elastin deposition and normal muscle cells in the muscle layer of diverticular diseased colon. The elastin is in a shortened form, which may account for the thickened, foreshortened bowel typically found at surgery [41].

The distal sigmoid is the narrowest portion of the colon, and the distal sigmoid narrows with age [42]. The law of Laplace states that wall tension is directly proportional to the pressure times the diameter. Thus, as contractile pressures (as measured by wall tension) remain the same and the diameter is decreased, there is an increase in pressure delivered to the bowel wall. A simple example of Laplace's law is blowing up a balloon. It is most difficult when there is no air in the balloon and becomes easier as the diameter increases. Similarly, increased pressures are required in the narrower distal sigmoid to propel stool. As the lumen narrows with age, higher pressures are required. This increased stress further damages the colon, causing decreased elasticity and more loss of tensile strength [40]. Comparison studies show that populations with a low incidence of diverticular disease have stronger, more elastic distal colons than industrialized populations [42], presumably due to years of more bulky stools keeping the lumen diameter large. Furthermore, with increasing wall tension pressures, there must be a concomitant decrease in microvascular perfusion [43], possibly adding further weight to the vascular theory of free perforation of diverticulitis [15]. The resulting increased intraluminal pressure causes long-term changes in the bowel wall, including decreased tensile strength, decreased diameter, and vascular changes which predispose to diverticular disease and the more frequent perforation seen in the elderly.

Epidemiology

Diverticulosis is an entity particular to the dietary patterns of Western society. There are linear increases in size, number, incidence, and symptoms of diverticula with age [6, 44]. Diverticulae are commonly 5–10 mm in size and can occasionally be >2 cm. Giant diverticula have been described. Diverticulosis occurs in 2–5% of patients under age 40 and up to one-third of people over age 45. Two-thirds of people over age 85 have radiographic or pathologic evidence of diverticulosis [45]. Deckman and Cheskin [46] cited a prevalence in the USA as high as 33% with similar figures in European countries. In comparison, the prevalence in populations with higher per capita fiber intake is much lower. Diverticulosis is uncommon in developing parts of Africa and Asia and may be as low as 1% in Korea [35], with low incidences found in other similar populations [47–52].

Independent of age, prevalence is thought to be similar in men and women. However, in a large single institutional series by Rodkey and Welch [53], when sex and age were examined jointly, women over 70 years of age predominated over men by more than 3:1. The reverse was found in patients under 50 years of age, with more than twice as many men affected as women. This ratio was also substantiated by

Ouriel and Schwartz [54], who found a predominance of men in the under-40 age group.

Nonsteroidal anti-inflammatory drugs (NSAIDs) have also been linked to diverticular disease [55], and others have implicated NSAIDs as a potential cause of acute diverticulitis [56–58]. Steroids have been linked to diverticulitis as well. Steroids also mask symptoms of infection which may cause delays in diagnosis, resulting in poor prognosis [59–61].

Pathogenesis

Diverticulitis is the inflammatory process that originates within colonic pseudodiverticula. The particular mechanisms of both the local and systemic infections have not been well characterized. It has been hypothesized that diverticulitis constitutes the same end point of localized luminal obstruction found with other intraabdominal visceral inflammatory processes such as appendicitis and cholecystitis [62–64]. Obstruction of the neck of the diverticula, presumably with inspissated stool, creates a closed microenvironment characterized by fluid sequestration, stasis, and bacterial overgrowth. Deitch [65] showed that even in the absence of perforation, obstruction alone is sufficient for bacterial translocation across the intestinal barrier. As the diameter of the diverticulum expands to accommodate the increased intraluminal pressure, venous and then arterial pressures are overcome. This results in congestion, ischemic necrosis, and perforation. Others cannot find supporting pathologic evidence and suggest that perforation is likely the result of increased intraluminal pressure [46]. Activation of local and systemic inflammatory mediators, in combination with microscopic or macroscopic perforation and soiling of the peritoneum, leads to the clinical manifestations of the disease. The role of localized ischemia was discussed earlier [28].

Atypical, painful or chronic diverticular disease is a difficult-to-describe entity. It is described as chronic, intermittent left lower abdominal pain, not usually associated with typical findings of acute inflammation. Motility patterns may be abnormal in this subset of patients [67]. Pain is usually chronic, intermittent, and not associated with acute symptoms. Narrow stools and other changes in bowel habits may result. Attacks may come and go. Symptoms may be confused with irritable bowel syndrome. The diagnosis is difficult, with barium enema showing only diverticulosis and possibly spasm of the sigmoid colon. CAT scan does not reveal acute inflammation, and it does not respond to antibiotics or dietary modification. Endoscopic findings are generally nonspecific, although a tortuous colon may be found. Endoscopy may show edema or associated patchy colitis.

Treatment is aimed at relieving symptoms. Bulk agents (psyllium seed) and a high-fiber diet are usually helpful. Differentiating between irritable bowel syndrome and painful diverticular disease is difficult as symptoms of bloating, distention, and intermittent nonspecific abdominal pain are common. Fortunately, IBS and painful diverticular disease are treated similarly with high-fiber diet and symptom control with moderate success. Uncommonly, sigmoid resection is required to produce relief. Appropriate patient selection is paramount in identifying who may respond to operative intervention and those who will not. When well chosen, sigmoid resection will relieve pain in 79–80% of patients [67].

Symptoms

The spectrum of disease produced by diverticula ranges from completely symptom-free to vascular collapse secondary to systemic sepsis from peritonitis. About 10–25% of patients with diverticulosis progress to diverticulitis [68, 69]. Most of these patients never come to surgical attention [68, 69]. A small number, estimated at fewer than 25% of those with diverticulitis, require inpatient management of their disease [70]. Complicated cases involving sepsis, obstruction, fistula formation, or peritonitis constitute approximately 40% of all those admitted. Older patients present more often with complicated disease. The elderly present with diffuse peritonitis up to twice as frequently as younger patients [29, 31].

Typically, patients with diverticulitis seek medical care owing to mild or moderate peritoneal irritation often accompanied by a change in bowel habits. Crampy left lower quadrant pain is also common. Approximately two-thirds of patients complain of constipation or diarrhea [71]. Other associated symptoms may include a palpable mass, abdominal distension, dysuria, excessive flatus, nausea, and vomiting. About 30–40% of patients have occult blood in their stool [3]. Fever and pain are the most consistent indicators of acute disease, occurring 45% of the time. Septic shock with diffuse peritonitis may be the presenting picture. With the presence of a redundant sigmoid colon, suprapubic or right lower quadrant pain may manifest. Occasionally, the diagnosis of appendicitis is the indication for surgical exploration when a redundant sigmoid colon with diverticulitis is found to be the culprit.

Considerable diagnostic overlap exists between diverticulitis and other acute abdominal processes. The spectrum of differential diagnoses ranges from relatively common urinary tract infections in the elderly to inflammatory bowel disease, colon cancer, closed loop obstruction, and ischemic bowel. These diagnoses and causes of abdominal pain must always be kept in mind during the initial evaluation.

Symptoms of diverticular fistulas may lead to an accurate preoperative diagnosis. Pneumaturia and fecaluria are diagnostic of an enteric-vesicular fistula and in the appropriate patients are highly suggestive of a diverticular origin. Similarly, flatus or stool via the vagina leads to common bowel sources. Thigh abscesses, especially those with foul-smelling anaerobic pus, may originate from a diverticular abscess with tracking along the psoas muscle onto the skin.

Many investigators have found atypical presentations of diverticular disease in the elderly [29, 72–76]. Wroblewski and Mikulowski [74] noted the absence of typical manifestation of peritonitis in the elderly to be associated with a poor outcome. They also found an absence of abdominal pain in half of their patients with peritonitis. Intraabdominal abscesses are the most common cause of fever of unknown origin in the elderly [77]. Others noted that elderly patients with intraabdominal infections have hypothermic temperatures more frequently than young patients. Similarly, old patients have less nausea, vomiting, diarrhea, and fever compared to the young [72]. Acute abdominal pain is more likely to require surgery in the elderly [78, 79]. France et al. [73] examined 12 old patients who died of diverticulitis: 75% did not have symptoms typical of their disease, 3 of the 12 did not have abdominal symptoms, and another's symptoms did not warrant further investigation. Generalized peritonitis occurs in up to one-half of old patients [29, 30]. Old patients require operations more frequently, have free perforation more commonly, and have higher mortality rates than young patients [29–32, 80]. Watters et al. [29] attempted to explain this difference. They found that the mean time from the onset of symptoms to hospitalization for old and young patients with generalized diverticular peritonitis was the same. Thus, old patients have peritonitis and free perforation more frequently than the young do, and it is not due to a delay in seeking medical care. This finding suggests that the severity of disease in the elderly is determined early in its course and is independent of the passage of time. Another possible explanation is that symptoms begin later in the course of the disease in the elderly. The former explanation further supports the theory that ischemia is the cause of the more frequent diffuse peritonitis found in the elderly.

Diagnosis

Diverticulitis is usually diagnosed based completely on clinical grounds. This presents a unique problem in the elderly because, as previously shown, they often present atypically, and abdominal pain is minimal or absent. A history of known diverticula seen by barium enema or endoscopy often aids the clinician. However, it is unnecessary to have previous knowledge of diverticula in a particular patient, as more elderly

patients have diverticula than do not [46]. Useful serologic and hematologic tests include a complete blood count, serum electrolytes, urinalysis, and in the case of suspected ischemic bowel, arterial blood gas measurement for acid–base disturbances. White blood cell (WBC) can be normal in almost one-half of older patients [32]. Physical examination usually reveals peritoneal irritation to some extent. Mild left lower quadrant tenderness to generalized peritonitis may be found. Rectal examination may reveal a pelvic abscess.

Several diagnostic modalities are helpful for establishing the diagnosis of diverticular disease and assessing the extent of inflammation. In preceding decades, contrast enema was the test of choice for diagnosis. Previous practice parameters of the American Society of Colon and Rectal Surgeons [81] cite a sensitivity of 94%, an accuracy of 77%, and a false-negative rate of 2–15% with water-soluble enemas. Contrast enemas in the setting of diverticular disease have been shown to be less reliable in identifying neoplastic growth compared with colonoscopy [82]. Radiographic findings include intramural or extramural sinus tracts, filling of the abscess cavity, or inferred extramural compression or spasm of the bowel lumen.

Ultrasonography may also provide useful information in the setting of suspected diverticular disease. Investigators have found it to be 84–98% sensitive [83–85]. Ultrasonography can detect abnormal segments of bowel, those with mural thickening, peridiverticular inflammation and abscess, and linear echogenic foci suggestive of fistulous tracts. Unfortunately, this technique is both operator-dependent and limited by the body habitus of the patient. Zielke et al. [86] found that surgical residents were able to accurately diagnose diverticulitis in 84% of patients, with a 16% false-negative rate.

Computed tomography (CT) has emerged as the imaging modality of choice for evaluating suspected diverticulitis [87–91]. Though in some studies it is comparable to contrast enema, other investigators have found a clear advantage regarding its diagnostic sensitivity and specificity [92]. Hulnick et al. [91] found that CT not only stages the extent of the inflammatory process more accurately, but it also better differentiates the varying gradations of pericolic inflammation. Furthermore, CT has the distinct advantage over a contrast enema because of its ability to identify both the intraluminal and extraluminal components of diverticular disease. It is also the diagnostic modality of choice for identifying colovesical and colovaginal fistulas. Findings suggestive of diverticulitis include inflammation of the pericolic fat, thickening of the sigmoid mesocolon, pericolic phlegmon, visualization of colonic diverticula themselves, and thickening of the colonic wall (see Fig. 67.1). CT is helpful for demonstrating the manifestations of intraabdominal abscess, particularly abscesses amenable to percutaneous drainage [87–91]. Despite these modalities, the diagnosis of diverticulitis can be obscure in the elderly [74].

FIGURE 67.1 Acute diverticulitis of the sigmoid colon with paracolic fat stranding.

Endoscopic evaluation is reserved until after the acute phase has resolved; it is used mainly to rule out carcinoma. CT colography is a new modality that noninvasively evaluates the contour of the colon lumen. It is especially helpful in cases where, due to stricture or obstruction, a colonoscope cannot traverse the diseased bowel. Colography can ensure that the proximal bowel does not harbor unsuspected neoplastic lesions.

Treatment

Prevention of Symptoms

High-fiber diet has been shown to decrease the formation of diverticulae in rats [19]. Examination of population-based per capita fiber intake reveals less diverticular disease with high average fiber intake [47, 50, 51]. High fiber intake in American males decreases the risk of diverticular symptoms. There is no evidence that increasing fiber intake can cause diverticulae to regress. It follows that high-fiber diet should be suggested to decrease the chance of diverticular symptoms [93]. There is no evidence to support the concept of avoiding food particles that can obstruct the neck of diverticulae. Accordingly, avoidance of seeds, nuts, popcorn, etc., has not been shown to cause acute disease. Most physicians suggest a high-fiber diet with bulk-producing supplements (psyllium seed) for patients with asymptomatic diverticulosis [94]. Fiber has been shown to decrease intraluminal pressures and colonic transit time [27, 95–97]. It also decreases symptoms attributed to diverticular disease [94, 95, 97–100]. Antispasmodic medications have not been shown to help.

Uncomplicated Diverticulitis

Most acute diverticulitis are treated by primary physicians on an outpatient basis. Those with only mild tenderness, no clinical peritoneal signs, and the ability to achieve satisfactory pain control and tolerate adequate fluids orally may be treated empirically on an outpatient basis [6]. Treatment consists of oral antibiotics covering anaerobic and gram-negative bacteria for at least 7 days and liquid diet until resolution of symptoms. Significant systemic signs of infection including high fever and leukocytosis suggest the need for hospital treatment. Resolution is common. There is no place for outpatient management in the setting of significant concurrent medical disease, immune compromise, or in those with altered mental status, or patients without appropriate supervision.

Immune-compromised patients have a more aggressive disease path, are more likely to present with perforation, and have higher morbidity and mortality rates [60, 101]. Perkins et al. [101] found a 100% failure rate with conservative treatment of immune-compromised patients. Early surgical management is appropriate in this patient population. Due to the aggressive nature of diverticulitis, some have suggested elective sigmoid resection in patients with a single prior attack when they are candidates for organ transplantation with its attendant long-term immune suppression [102]. Patients on continuous peritoneal dialysis represent a special dilemma. CT scanning is usually nondiagnostic, and delay in treatment results in poor outcomes. After treatment, very few will be able to remain on peritoneal dialysis [103].

Patients who fail in outpatient therapy or who present with significant systemic symptoms should be admitted to the hospital. Hospital treatment consists of complete bowel rest and parenteral broad-spectrum antibiotics to cover anaerobic and gram-negative bacteria. Triple-antibiotic or single-agent therapy are both effective. Nasogastric suction is required only with persistent vomiting or evidence of bowel obstruction. Laboratory evaluation includes a complete blood count and urinalysis. CT should be done to confirm the diagnosis, quantify the extent of inflammation, and identify possible complicated diverticular disease. Conservative treatment of acute uncomplicated diverticulitis leads to resolution of symptoms in 70–100% of cases [2, 3, 46, 47, 53, 87, 104]. Oral intake is resumed with disappearance of symptoms. Following hospital discharge, oral antibiotics should be continued for 7–10 days. With complete resolution of the inflammation, patients should have endoscopic or radiographic evaluation of their colon to rule out carcinoma, and they should be started on long-term fiber supplementation. Psyllium seed or hydrophilic colloids have been shown to reduce recurrence by up to 70% [100]. Old studies suggest that one-fourth of patients who recover from their first attack will have further attacks requiring

hospitalization [2, 105]. A recent study with a median 5-year follow-up revealed that <2% of patients reported more than mild symptoms [106].

The goal of elective sigmoid resection is to reduce the potential for re-presentation with complicated disease requiring emergency colon surgery with its attendant increased complication and mortality rates. Hartmann's resection with temporary ostomy formation is often a result of these emergent operations. Ostomies formed during emergency operations are not reversed in a significant minority of patients [107]. Over the last decade, there has been a major shift in decision making regarding elective resection and diverticulitis. The natural history of disease is not well known. Practice parameters from the American College of Gastroenterology, American Society of Colon and Rectal Surgeons, and the European Association of Endoscopic Surgeons have all supported elective resection after 1–2 attacks, especially in younger patients [108–110].

A recent population-based study of first-event-hospitalized diverticulitis patients [111] showed that only 5% of older patients who did not require emergency surgery at first presentation ultimately required emergent colectomy/colostomy formation. Some have estimated the risk of colostomy after one attack of mild diverticulitis at one in 2,000 patient years of follow up [112]. A multicenter Kaiser Permanente study [113] followed 3,165 patients admitted with diverticulitis for a mean of 8.9 years. They found a 13.3% recurrence rate in patients treated nonoperatively, one quarter had re-recurrences. Old age was associated with a lower recurrence rate (12.2%). They also noted an increased risk of further attacks with each additional recurrence. They believe that no patients had colostomies in this group.

These findings have led to a change in the traditional suggestion that patients undergo elective sigmoid resection after 1–3 documented attacks. The frequency and severity of attacks, crescendo attacks, and the medical comorbidities should be considered when deciding to suggest elective sigmoid resection. The number of attacks should not be a major factor in decisions regarding timing of surgery. Most patients with perforating diverticular disease present with such at their first attack [111–116].

As seen above, very few patients require colostomies after initial successful nonoperative management. Further, the severity of disease, as measured by CAT scan during the first attack, may be a predictor of aggressive disease and the future need for operative intervention [117]. The number of attacks required to suggest elective resection is in dispute at this time. Salem [114] used a Markov model to evaluate the lifetime risk of death and colostomy as well as care cost and quality of life and elective resection for diverticulitis. They conclude that performing colectomy after a fourth attack in 50-year-old patients would result in 0.5% fewer deaths, 0.7% fewer colostomies, and save over \$1,000.00 per patient.

Using 35-year-old patients in the model resulted in 0.1% fewer deaths, 2% fewer colostomies, and over \$5,400.00 saved per patient. Clearly, delaying elective resection appears beneficial to patients and the cost of health care.

Elective resection for diverticulitis results in acceptable results. Thorn et al. [118] followed 75 consecutive elective sigmoid resections for diverticulitis. They found 13% major perioperative complications. Eight percent had recurrent diverticulitis during the follow-up period. Two-thirds of patients classified their results as good or excellent. IBS type symptoms in the preoperative period predicted less successful outcomes. Further along this line, a 21-year retrospective postresection study [119] showed that patients without histologic evidence for acute or chronic inflammation were seven times more likely to have persistent postoperative pain and twice as likely to have recurrent “diverticulitis” as those with histologic evidence of inflammation. Elective resection after one attack in patients requiring long-term immunosuppression is appropriate to prevent future sepsis. Elective resection may be required if cancer cannot be ruled out [62].

Surgical Technique

Elective sigmoid resection after resolution of the acute inflammation should include adequate mobilization of the proximal bowel to provide a tension-free anastomosis. The proximal bowel need not be devoid of diverticulosis, but the bowel must be soft, supple, and free of diverticular thickening. Resection should include all thickened, diseased bowel. Splenic flexure mobilization is occasionally required to achieve these goals. Distal resection must include removal of the entire sigmoid to the rectum to significantly reduce recurrent attacks [120]. No diverticula should be left distal to the anastomosis. The site of distal transection should be at the point where the taenia coli are lost, signifying the beginning of the intraperitoneal rectum.

Laparoscopic techniques have evolved significantly in recent years. Laparoscopy has been used in all types of diverticular resections and to drain abscesses not amenable to percutaneous CAT approaches. Laparoscopic colectomy in the elderly is safe and effective as well [121]. Laparoscopy is safe with complicated diverticulitis as well [122]. Laparoscopic surgery is successful in treating fistula disease as well, with laparoscopic colovesicle and colovaginal fistula operations becoming more common [123, 124]. Many studies have showed that laparoscopic approach to this disease is safe and effective and may confer benefits to patients compared with traditional open surgery. Decreased complications, faster recovery of bowel function, and oral intake have been seen in older patients [125, 126]. Pulmonary function is better preserved, and a host of stress measurements show

that less stress is imparted to laparoscopically treated patients compared with open techniques [127]. These benefits have been shown to be enhanced in older patients compared with younger ones [128]. Older patients also enjoy fewer cardiopulmonary complications with laparoscopy [129]. Laparoscopy has allowed more elderly patients to be discharged home rather than to rehab facilities compared with open surgery [125, 130]. Finally, Senagore [131] showed a lower direct cost in elderly patients undergoing laparoscopic resection compared with those having open surgery.

As experience and instrumentation improves, laparoscopy will most likely become the standard approach for most elective diverticular surgery and many urgent and emergent procedures as well. The most recent Practice Parameters published by the American Society of Colon and Rectal Surgeons conclude: When a colectomy for diverticular disease is performed, a laparoscopic approach is appropriate in selected patients [132].

Up to one-third of all patients admitted to the hospital require urgent or emergent surgery [2, 44, 45, 56, 105]. Up to one-half of elderly patients present with generalized peritonitis requiring operative intervention [29]. Similarly, more older patients with diverticulitis require urgent or emergent operations compared with younger patients [30]. Most patients requiring urgent or emergent surgery are undergoing their initial episode of diverticulitis [3, 113]. Hinchey et al. [133] described a grading system for acute diverticulitis. Stage I is confined pericolic abscess. Stage II is distant abscess. Stage III is generalized peritonitis caused by rupture of a pericolic or pelvic abscess, “noncommunicating” with bowel lumen because of obliteration of diverticular neck by inflammation. Stage IV is fecal peritonitis caused by free perforation of a diverticulum (“communication”). Emergent surgical treatment aims to relieve sepsis, remove the diseased bowel, minimize mortality and morbidity, and avoid stomas with their concomitant second operation to restore bowel continuity. Options include resection with primary anastomosis, resection with proximal colostomy and closure of the distal end (Hartmann’s procedure), and diversion with drainage alone. The latter plays only a small role today, with only the most ill and unstable patients unable to tolerate removal of the infectious foci. Diversion alone leaves a column of undrained stool above the perforation that can further contribute to the septic process [134, 135].

Resection with primary anastomosis for acute disease is often possible with gentle preoperative bowel preparation and localized sepsis [134]. Mobilization of the colon should begin in an unaffected area to facilitate entrance into normal planes of dissection. The retroperitoneal structures (ureters and gonadal vessels) can be swept dorsally, elevating the sigmoid colon. Ureteral catheters can be helpful for acute inflammation and occasionally for elective resections [136]. Hartmann’s resection with diverting colostomy has been

traditionally reserved for patients with unprepared bowel. Hartmann's procedure carries significant complication and mortality rates [137].

More recently, primary resection and anastomosis in well-selected acute disease has been successful [138]. Selection includes minimal local sepsis and well-nourished patients. On-table lavage is an option in patients with proximal solid stool and minimal contamination. Adequate diverticular resection requires removal of the distal sigmoid from the rectum when restoring bowel continuity after Hartmann's procedure. Removing the sigmoid from the rectum decreases recurrences of diverticular disease [120]. Furthermore, using the distal sigmoid instead of rectum for the anastomosis was found to be a risk factor in the development of postoperative colocutaneous fistulas [139].

Complicated Diverticular Disease

Complicating factors associated with diverticular disease include abscess formation, free perforation, fistula formation, obstruction, and bleeding. The presentation of complicated diverticular disease occurs in up to 32% of hospitalized patients [87] and in more than 50% of the elderly [29]. Bleeding diverticular disease is discussed in Chap. 45. The vast majority of perforating diverticulitis occurs during the first attack [140, 141], and the incidence of nonperforating complicated diverticulitis is decreasing compared with past studies [117]. In contrast, the incidence of perforating diverticulitis may be increasing [141]. Complicated diverticulitis is associated with significant morbidity and mortality, and the need for operative intervention should be continually reassessed. Treatment of complicated diverticular disease requires accurate diagnosis and staging. The goal of treatment of complicated diverticular disease is to minimize morbidity and mortality, avoid ostomy formation and the number of subsequent operations. To achieve these goals, nonoperative techniques can convert complicated disease to medically manageable disease, thereby allowing elective resection with primary anastomosis.

Hartmann's procedure is associated with high morbidity and mortality rates [136, 142, 143]. Retained colostomy rates after Hartmann's operation range from 5 to 58% [136, 144]. A large review of Hartmann's procedure [107], where diverticulitis was the indication for almost 60% of operations, found a 14% mortality rate and that more than 40% of colostomies were not reversed. In a related study [145], a higher than expected mortality rate was found in older patients undergoing colostomy reversal. And, in these older patients, only 30% of colostomies created were reversed! Surgeons operating emergently on the elderly need to ensure proper placement and construction of these temporary ostomies, as many of

them are permanent to the patient. Furthermore, colostomy closure is associated with significant complication and death rates, especially in the elderly [144]. Eisenstat et al. [146] recorded a lower mortality rate for complicated diverticular disease treated with elective resection than that treated with staged surgical procedures. Avoiding a stoma with its concomitant second operation is a major goal of operative treatment for complicated diverticular disease. Accurate preoperative diagnosis is helpful, as up to 25% of patients explored for abscess or fistula have a perforated cancer [147].

Abscess formation is the most common complication of acute diverticulitis, occurring in 32–68% of complicated diverticular cases [88–90, 148]. A wide spectrum of presentations may result: small occult abscesses; scrotal, buttock, or thigh abscess; and sepsis due to a large abscess. Diagnosis is best made with CT [8, 149]. Treatment is aimed at relief of the sepsis and the diverticulitis. Small pericolic abscesses or phlegmon may be managed conservatively with bowel rest and broad-spectrum intravenous antibiotics. Elective, single-stage sigmoid resection with primary anastomosis can be done with resolution of symptoms. If symptoms worsen or are not alleviated, repeat CT scan with percutaneous drainage of the abscess should be considered (see Figs. 67.2 and 67.3). Exploration is reserved for patients whose abscesses are not amenable to percutaneous drainage or who fail in conservative management. Primary anastomosis is possible if the proximal and distal bowel is healthy and the perforation is contained, and if a gentle preoperative mechanical preparation has been done [144]. The patient's underlying medical diseases and acute physiologic status must obviously be considered.

FIGURE 67.2 Diverticular abscess with well-formed, enhancing wall.

FIGURE 67.3 Percutaneous drainage of the abscess.

Large abscesses, including more distant pelvic abscesses, and smaller ones that do not respond to conservative treatment should be referred quickly for possible percutaneous drainage under CT guidance [150]. Percutaneous drainage of diverticular abscesses is associated with a success rate of 62–100% [88, 89, 150–154]. Following placement of a drainage catheter and aspiration of the pus, repeat radiologic evaluation should be undertaken to assess not only resolution of the abscess cavity but also to identify potential fistulous communications to the small or large bowel. In the setting of appropriate drainage, treatment should progress as for uncomplicated diverticulitis. The catheter may be removed when the drainage stops or when complete collapse of the abscess cavity has been shown by sinography. At discharge, the catheter may also be left in place and removed during subsequent elective sigmoid resection [88]. The presence of a persistent colocutaneous fistula does not preclude elective resection with primary anastomosis [136]. Such a course of treatment allows complicated disease to be transformed nonoperatively to disease that responds to medical treatment, thereby avoiding emergent surgery with stoma formation. Subsequent elective sigmoid resection with primary anastomosis after resolution of inflammation (in about 6 weeks) becomes the only operative intervention required [154]. This has become the standard treatment for diverticulitis complicated by abscess formation.

Stabile et al. [88] followed three patients who refused surgery after catheter drainage for large abscesses. One required resection after a repeat diverticulitis attack 7 months later. The second required permanent catheter drainage for

recurrent and persistent abscesses. The third died in hospital of sepsis. Ambrosetti et al. [32] followed one patient without operation after percutaneous drainage who required elective resection 11 months later owing to stenosis. The authors suggested that occasional small mesocolic abscesses can be managed without operation, but they stated that pelvic and abdominal abscesses behave aggressively and require surgical treatment. Kaiser [155] found that 41% of patients who managed with percutaneous abscess drainage without surgery developed severe sepsis. Conversely, Broderick-Villa [113] found no increase in recurrence rates after abscesses were percutaneously drained and treated without elective operation compared with uncomplicated diverticulitis followed nonoperatively. Others suggest a conservative approach after drainage is appropriate as well [156]. As with elective resection after uncomplicated diverticulitis, there may be a change of surgical decision making. At this time, all patients, with the possible exception of those with small mesocolic abscesses, which are treated with percutaneous drainage, should have elective sigmoid resection after resolution of inflammation to prevent future complications [132].

Pelvic abscesses can be drained transrectally and transvaginally in women as well. These techniques are being replaced by CT-guided drainage but should remain in the surgeon's arsenal. If large abscesses cannot be drained adequately or if sepsis does not resolve, operative exploration is required. Gentle preoperative mechanical bowel preparation can be performed in well-selected patients, and with normal proximal and distal bowel, resection and primary anastomosis can be performed safely [144]. The use of Hartmann's procedure is reserved for most other patients. One should remember that restoring bowel continuity after Hartmann's procedure has high morbidity and mortality rates, and a large percentage of "temporary" stomas become permanent [134, 143–145].

A few important technical aspects of resection must be emphasized. When possible, care should be taken in the face of peritonitis to avoid opening noninfected tissue planes such as the presacral space and the splenic flexure area. These areas are known to invite abscess formation and are best left intact and free from contamination by the infectious process. Ureteral catheters may be employed, as the inflammatory process may obliterate the normal tissue planes and allow the ureters to be drawn into the inflammatory process [157]. The reader is referred to standard surgical textbooks for other technical aspects of sigmoid resection.

Perforating diverticular disease is the most virulent form of this disease. The vast majority of patients with perforating diverticulitis have no previous history of diverticulitis [112–114]. It is important to consider these patients separately from other complicated diverticulitis patients. Perforating diverticulitis has higher operative mortality (12–21% vs. 0–2.6%)

compared with nonperforating complicated diverticulitis [53, 116]. Free perforation of diverticulitis generally presents as acute sepsis or an acute abdominal crisis and some degree of shock. It occurs in approximately 10% of complicated cases [88]. More importantly, up to 50% of elderly patients present with diffuse peritonitis [29, 30]. Rapid hydration with correction of electrolyte abnormalities is necessary. Broad-spectrum antibiotics are administered preoperatively. Immunocompromised patients may not exhibit classic abdominal findings. Physical examination and CT scans generally yield the diagnosis. A large number of old patients with peritonitis lack abdominal pain as a finding [74], so a high index of suspicion is required when treating them. Emergent exploration with aspiration of pus, cleansing of fecal material, resection of the diseased bowel, and proximal end colostomy with oversewing of the distal stump (Hartmann's operation) are performed [158–160]. Only rarely are patients so sick that diversion and drainage without resection is appropriate [159, 161]. In fact, one study [134] found higher mortality among patients treated with diversion only compared to those who underwent resection, despite more steroid use and fecal peritonitis in the resection group. The mortality rate associated with fecal peritonitis is as high as 35% [134, 159, 161].

Fistula formation occurs in approximately 2% of diverticulitis cases but accounts for up to 22% of patients requiring surgery [144, 159, 162, 163]. Multiple fistulas are uncommon [163]. Fistulas develop when inflammation or abscesses develop in close proximity to adjacent organs. The inflammatory process invades the adjacent normal organs and causes decompression, which spontaneously converts the acute complicated infectious process to controlled, drained, simple diverticulitis. It is diagnosed often on clinical grounds, and diagnostic tests are used to rule out cancer and other diagnoses. Expensive, complex testing is often unnecessary. In general, single-stage resection with primary anastomosis can be performed in a fashion similar to that used for complicated diverticulitis treated with percutaneous abscess drainage.
